THE PHYSICAL REVIEW

AN X-RAY SEARCH FOR THE ORIGIN OF FERROMAGNETISM

BY J. C. STEARNS

RYERSON PHYSICAL LABORATORY, UNIVERSITY OF CHICAGO

(Received November 19, 1929)

ABSTRACT

A sensitive null method, employing two crystals and two ionization chambers, was used to detect any change in intensity of an x-ray beam reflected from a magnetic crystal, when this magnetic crystal was magnetized. This method was capable of detecting from 1.0 to 0.1 percent change in intensity, according to the intensity of the reflected beam. Crystals of magnetite and silicon steel were used. No change of intensity was observed, although the theoretical change was several times that which could have been detected. The change in intensity of the x-ray beam was computed on the basis of the alteration of the structure factor due to orientation of electronic orbits by the magnetic field. It is concluded that electrons revolving in orbits within the atom cannot account for ferromagnetism. The models of Honda and Ehrenfest are briefly discussed. On the basis of present atomic models and present experimental evidence it appears that the ultimate magnet should be identified with the spinning electron.

SEVERAL experiments have been reported¹ in which x-rays have been used to study the nature of the ultimate magnetic particle. From these it has been concluded that the most minute crystal aggregations in solid iron are not oriented by a magnetic field, that the ultimate magnet cannot be a group of atoms such as the chemical molecule, and finally, that the atom as a unit cannot account for ferromagnetism. On the basis of present atomic models three possible ultimate magnetic particles remain: the atomic nucleus, the spinning electron, or electrons revolving in inner orbits. The following experiment was performed primarily to ascertain whether electrons revolving in the inner orbits may be responsible for ferromagnetism.

THE EXPERIMENT

The apparatus used is indicated in Fig. 1. It is essentially a refinement of that employed by A. H. Compton and Rognley. The x-ray tube had a water-cooled molybdenum target, and could be operated at 35 milliamperes

¹ M. de Broglie, *Le Radium* 10, 186 (1913). K. T. Compton and E. A. Trousdale, *Phys. Rev.* 5, 315 (1915). A. H. Compton and Oswald Rognley, *Phys. Rev.* 16, 464 (1920). T. D. Yensen, *Phys. Rev.* 31, 714 (1928).

and 50 kilovolts. One portion of the x-ray beam fell on C' , a crystal of magnetite or silicon steel, which reflected the $K\alpha$ line into ionization chamber I' . Another portion of the beam passed above C' and was incident upon C'' , a calcite crystal, from which the $K\alpha$ line was reflected into chamber I'' . The electrodes of the ionization chambers were connected to the same pair of electrometer quadrants, while one chamber was maintained at a positive and the other at a negative potential. S' and S'' were adjustable slits. An intense beam of x-rays was allowed to fall upon the crystals, and the slits were adjusted until the electrometer charged up at a very slow rate. With other conditions unaltered the crystal C' was magnetized and the rate of deflection of the electrometer again taken. In order to make a comparison of successive readings, two readings taken with the electromagnet unenergized alternated with two successive readings with the magnet energized. From a set of twenty-five to fifty readings for each order the mean change of

Fig. 1. Diagrammatic sketch of apparatus.

rate due to magnetization was determined. A sheet of aluminium, which absorbed four percent of the beam was then placed in front of S' and the resulting change in the rate at which the electrometer was being charged observed. Then: $\text{Change of rate due to magnetization} / \text{Change in rate due to absorption by aluminium} \times 4 = \text{percent change in intensity due to magnetization}$.

The electromagnet M had a laminated core about which were wound five thousand turns of number 23 copper wire. The air gap was about 2 mm. Demagnetization was secured by successively reversing and gradually decreasing the current. The magnetic induction was measured by means of a commercial flux meter. The calcite crystal was fixed to a non-magnetic mounting which was placed outside the magnetic field and could be rotated independently of the electromagnet and the magnetic crystal. The x-ray tube was mounted inside a heavy wrought iron pipe, the ends of which were closed by iron plates one inch in thickness. The ionization chambers were duplicates, and each was filled with argon.

DISTURBING EFFECTS AND THEIR ELIMINATION

It was necessary to mount the crystal C' with unusual care in order to avoid motion of the crystal relative to the incident beam when the magnet

was energized. It was found also that the establishing of the magnetic field sufficient in strength to produce magnetic saturation in the crystal shifted the electrometer needle through several degrees, and changed the current sensitivity of the electrometer. By using a mica needle plated with a suitable combination of gold and platinum this effect was overcome. In testing the sensitivity the deflection rates were compared with and without the magnetic field, using radium emanation tubes as a source of ionization.

Before the tube was enclosed in the iron pipe, the field in the region of the x-ray tube was found to be sufficient to move the focal spot 0.2 or 0.3 mm. This shift produced a change in the intensity of the reflected x-rays of the order of 1 percent, which changed in sign with a reversal of the field. When the tube was placed in the iron pipe, tests showed the shielding to be adequate.

CALCULATION OF CHANGE IN REFLECTION DUE TO ORIENTATION OF AN ELECTRON ORBIT

The following method was used in computing the theoretical change in the intensity of the reflected beam due to K or L electrons being oriented by an external field so that their magnetic moments were parallel to this field. A. H. Compton² shows that

$$W_n = K F_n^2, \quad (1)$$

where W_n is the total energy diffracted by a small crystal and F_n is the structure factor of the atom, while the subscript n refers to the order in question, and K is a factor of proportionality. If the primed letters refer to the energy and structure factor respectively when the crystal is magnetized and the unprimed letters to the same quantities when the magnetic crystal is unmagnetized, then

$$\frac{W'}{W} = \frac{(F_n')^2}{(F_n)^2} = \frac{[F_n + (F_n' - F_n)]^2}{(F_n)^2} = 1 + \frac{2\Delta F_n}{F_n}. \quad (2)$$

neglecting higher powers of ΔF_n . To calculate the change in intensity it is thus necessary to know the number of atoms affected by the magnetic field and the structure factors of the atom for the order in question when the crystal is magnetized and unmagnetized respectively.

The structure factor³ for the n th order of an electron moving at random over the surface of a spherical shell of radius r is

$$F_{en} = \frac{\sin 2\pi nr/D}{2\pi nr/D}, \quad (3)$$

where D is the grating space of the crystal. If magnetizing the crystal perpendicular to the reflecting face causes the orbit of an electron to lie in the plane of the reflecting face, its structure factor becomes unity, since the waves reflected by it are in phase with those from the middle of the atomic

² A. H. Compton, "X-rays and Electrons" p. 125.

³ Reference 2, p. 148.

layer. If without the magnetic field the orientation of the orbit is random, then

$$\Delta F_{en} = 1 - \frac{\sin 2\pi nr/D}{2\pi nr/D} \quad (4)$$

If, however, the crystal is magnetized parallel to the reflecting face, and the electron in question moves in a circle whose plane is perpendicular to the reflecting face, the structure factor for this electron becomes a Bessel function of the zero order,

$$F_{en}' = J_0(2\pi nr/D) \quad (5)$$

ΔF_{en} is then found in the same manner as in the preceding case.

If ΔF_{en} is the change in structure factor for each electron whose orbit is turned by the magnetic field, and if f is the number of electronic orbits per atom thus turned, the average change in structure factor is

$$\Delta F_n = f\Delta F_{en} \quad (6)$$

From Eq. (2) it follows that the ratio of the intensities when the crystal is magnetized and unmagnetized respectively is

$$(W'/W) = 1 + 2f(\Delta F_{en}/F_n) \quad (7)$$

To find the ratio f of the number of orbits oriented to the number of atoms, we may assume that each electronic orbit has a magnetic moment of one Bohr magneton. This ratio then becomes

$$\frac{1}{5589} \times \frac{\text{saturation intensity of magnetization}}{\text{number of atoms per molecule}} \times \frac{\text{molecular weight}}{\text{density}}$$

On this basis, in the case of magnetite, half of the atoms will have one atom oriented, i.e. $f=0.5$ while for silicon steel three orbits per two atoms will be turned around, i.e. $f=1.5$.

The structure factor F_n of the atom for any order may be determined if the structure factor for the first order is known and if the relative intensity reflected in each order is known. Equation (1) could then be used to give the structure factor. The ratio Z/F of the atomic number to the structure factor for the first order does not vary greatly with different atoms. In the cases of sodium and chlorine this ratio is 1.45 and 1.25 respectively. It is thus reasonable to assume the structure factor for the first order of the iron atom to be about 20 and that of the oxygen atom to be about 6.5. The intensities for the first three orders from the 110 planes of iron have been measured, thus permitting direct substitution* in (1) to find the atomic structure factor for orders 1 and 2. In the case of magnetite we may make use of the fact that the experimental values of F , for reflecting planes that are similar and similarly placed, are experimentally found to vary approximately inversely as the order. In computing the results for magnetite it has accordingly been assumed that $F_n = 20/n$ for the iron atom and $6.5/n$ for the oxygen atom.

* In making this substitution it is necessary to note that the factor K of Eq. (1) includes the trigonometric factor $(1 + \cos^2 2\theta)/\sin 2\theta$ (cf. A. H. Compton, reference 2).

For silicon steel these considerations are sufficient for determining $\Delta F_{en}/F_n$; but for magnetite it is necessary to know how a change in atomic structure factor will affect the intensity when the planes are neither similar nor similarly placed. Bragg⁴ has shown that the 110 planes may be represented by a single plane having a weight

$$56 + 112 \cos \pi n/4 + 168 \cos \pi n + 128 \cos \pi n/2,$$

where n is the order of the spectrum. The first three terms are the contributions due to the iron atoms, while the last term represents the contribution of the oxygen atoms. One may assume that both the oxygen and iron atoms are affected by the magnetic field or that either the iron or oxygen atoms have their electronic orbits oriented by the applied field. The first assumption seems the more reasonable and is the one here employed. It is seen that in the fourth order the planes made up of oxygen atoms cooperate with those made up of iron atoms, and a maximum change in intensity would result if only the oxygen atoms were influenced. This is due to the fact that the change in intensity per oxygen atom is greater than that per iron atom and the total number of atoms affected in either case must be the same. If only the iron atoms were influenced the effect would still be detectable, while the result given in the table is that based on the assumption that both iron and oxygen atoms are turned about by an external magnetic field. In the case of the fifth order all the planes may be represented by a plane of iron atoms of weight 90. In the sixth order all the 110 planes may be replaced by planes of iron atoms of weight 224 with planes of oxygen atoms of weight 128 midway between the iron planes. If both kinds of atoms are affected by the magnetic field the change in intensity would be too small to detect, while if the inner orbits of the iron atoms alone are oriented there should be a detectable increase in the intensity of the reflected x-ray beam. On the other hand a change in the oxygen atom alone should produce a decrease in intensity which would have been detected. Thus, by considering the fourth, fifth and sixth orders of magnetite, all possible cases have been considered, and the magnitude of the theoretical effect found is great enough for detection by the method employed whichever atom is affected by the magnetic field. The radii used for the K and L orbits were computed by use of Bohr's formula.

It appears that any reasonable assumptions regarding atomic structure factor or magnetic moment per electron orbit must lead to a predicted effect of the order of magnitude here calculated.

EXPERIMENTAL RESULTS

In the following table both the theoretical and experimental results are given. In the first column on the left the order is given. In the next column is given the theoretical ratio, $I'/I(K)$, of the integrated intensities reflected by the crystal when it is magnetized and unmagnetized respectively, assuming that the K electrons are the ones that orient themselves when the field is applied. In the next column is the same ratio for the case of the L electrons, while the last gives the experimental value.

2	1.0000	0.9993	1.0003+ .0006

In the above table the probable error of the mean is quoted.

It will be seen that the apparent changes in intensity of x-ray reflection due to magnetization are very small, and are of the magnitude to be expected from the probable error. There is thus no evidence for any change whatever in the reflecting power of these magnetic crystals due to magnetization. This conclusion is a considerable extension of the negative result of A. H. Compton and Rognley, for whereas in their experiments magnetite only was used, and this was magnetized only to one third saturation, here both the magnetite and the iron crystals were magnetically saturated. Moreover, these authors gave 1 percent as the precision of the experiment, whereas the more precise of the present experiments may probably be relied upon to 0.1 percent.

SIGNIFICANCE OF THE NEGATIVE RESULTS

Compton and Rognley¹ pointed out that a change of intensity of less than one percent in the fourth order when the crystal was only one third saturated was to be interpreted as meaning that the ultimate magnetic particle could not be the molecule or the atom as a whole unless the atom is surprisingly isotropic. The present data set a lower limit to the maximum displacement of atoms from their normal positions which could have occurred due to magnetization without being detected by this experiment. This distance could not have changed by as much as 1/2000 of the grating space without producing an effect that would have been detected by this experiment. It is also very improbable that the electrons revolving in inner orbits can account for ferromagnetism. In the fourth order in the case of magnetite the theoretical value is 35 times the experimental value, while in the second order for silicon steel the theoretical value is 9 times the experimental change.

Honda⁵ ascribes the magnetic property of an atom to the nucleus. Within the nucleus he pictures electrons and protons as revolving in opposite senses. This gives a large magnetic moment and a small angular momentum which would enable the nucleus to be oriented by an applied field. Such a system would be dynamically unstable. Further, as pointed out by Compton and Rognley, the magnetic properties of a substance are vitally affected by temperature, chemical combination and modification of the crystal structure as in the case of the Heusler alloys. On the other hand we cannot, by the most drastic of physical or chemical means, affect the radiation from radioactive substances, thus indicating that the nucleus is not influenced by external conditions. Thus while the results of this experiment are compatible with the theory of Honda, auxiliary evidence seems to indicate that the nucleus cannot be the ultimate magnet.

Ehrenfest has attempted to identify the ultimate magnet with an electron moving within a fixed orbit. In the absence of a magnetic field either sense of revolution is equally probable, while the application of an external magnetic field increases the probability that the sense of revolution of the electron will be such as to produce a magnetic moment in the direction of the field. When one tries to picture the process of magnetization, he is forced to imagine the orbits as turning suddenly, or the electron as suddenly reversing its direction in the orbit. If the whole orbit is able to turn it is difficult to conceive of it as a fixed orbit. If one is to account for hysteresis, energy must be dissipated when the probability of orientation in different directions changes. It then becomes difficult to see how hysteresis can be greatly reduced when the change in direction of magnetization is effected by means of a rotating magnetic field instead of an alternating field.

THE SPINNING ELECTRON AS THE ULTIMATE MAGNET

The results of other investigators indicate that neither minute crystal aggregations nor the chemical molecule nor the Rutherford type of atom as a whole can account for ferromagnetism. This experiment shows that it is highly improbable that electrons revolving in any of the orbits are responsible for ferromagnetism. Auxiliary evidence is against the conclusion that the nucleus may account for magnetic properties. It therefore appears that the ultimate magnetic particle should be identified with the spinning electron, as was long ago suggested by Parson⁶; and in accord with Uhlenbeck and Goudsmit's⁷ hypothesis of the origin of certain spectroscopic phenomena.

The author wishes to thank Professor A. H. Compton for proposing the problem, and Dr. R. D. Bennett for constructive suggestions during the course of the experimental work. The kind cooperation of Dr. T. Y. Yensen of the Westinghouse Electric and Manufacturing Company, Professor L. W. McKeehan of Yale University, and Mr. Norman Goss of the American steel and Wire Company in supplying large crystals of iron and silicon steel has made the completion of the work possible.

THE FORM OF THE X-RAY DIFFRACTION BANDS FOR REGULAR CRYSTALS OF COLLOIDAL SIZE*

BY CARLETON C. MURDOCK
CORNELL UNIVERSITY

(Received October 23, 1929)

ABSTRACT

The form of the diffraction bands of a very fine uniform crystalline powder has been computed for the (1, 0, 0), the (1, 1, 0) and the (1, 1, 1) planes for cubical and octahedral crystals of the regular system. The shape of the bands is approximately that of the Gauss error curve. Both the shape and the half intensity breadth vary from band to band and the variations are characteristic of the shape of the crystals. There is definite correlation between the form of the band and the direction of the corresponding Bragg planes with respect to the external features of the crystal. The mean breadth of the bands is nearly the same for cubical and octahedral crystals having the same volume. The values of the constant of Scherrer's equation are in general smaller than those computed by other investigators for the cubical case.

Secondary maxima.—A case is found in which secondary maxima of the intensity function would be sufficiently intense to be directly observable. It is pointed out that such an effect might lead to a false interpretation of the crystal structure of a very fine crystalline powder.

WHEN monochromatic x-rays are diffracted by a fine crystalline powder the diffraction bands are found to have a measurable width which is a function of the fineness of the powder. The effect is closely analogous to the low resolving power of a diffraction grating having a small number of lines. In this case we can regard the crystals as three dimensional gratings, the shape and size of which influence the form of the observed diffraction band. Scherrer¹ investigated the case of crystals of the regular (cubic) crystallographic system which are cubical in shape and gave for the half intensity breadth, B , of a diffraction band produced by the powder method,

$$B = \frac{K\lambda}{D \cos(\theta_0/2)} \quad (1)$$

in which λ is the wave-length of the incident x-rays, D , the length of one edge of the cube, and θ_0 , the angle between the diffracted and the incident ray. K is a constant whose value Scherrer found to be $2 [\log 2/\pi]^{1/2}$. Two other investigators treating more general cases have obtained results which reduce to Eq. (1) for the case of cubical crystals. They obtained slightly different values of the coefficient K . Seljakow² investigated the case of crystals of any

crystallographic system whose shape is a parallelopiped geometrically similar to the unit cell and whose edges are parallel to the crystallographic axes. v. Laue³ treated the case of parallelopipeds which have edges parallel to the crystallographic axes but which are not necessarily similar to the unit cell. His development brought out two interesting facts; viz. that the breadth of the diffraction bands depends upon the shape as well as upon the size of the parallelopiped; and in the general case, that the breadth is a function of the Miller indices of the band.

Considerable use has been made of Scherrer's equation in estimating the size of crystalline powders. Particular interest attaches to the investigation of colloidal preparations of such elements as gold, silver and nickel. These elements crystallize in face-centered cubic lattices and are normally of the octahedral form. In the investigations cited above no attempt has been made to determine the shape of the diffraction band. The shape of the band should depend upon the Miller indices of the band, the shape of the crystals, and, if the crystals are not of uniform size, upon the distribution of size. It seemed desirable to investigate the theoretical breadth and shape of several diffraction bands for crystals of octahedral as well as cubical shape.

The general procedure for computations of this sort is given by v. Laue³ and in the following discussion his notation is generally followed. Assume a parallel beam of monochromatic x-rays incident upon a crystal in a direction which we shall specify by the unit vector s_0 . Consider the rays diffracted by the crystal in the direction of the unit vector s . The intensity of the diffracted beam may be expressed⁴ as a periodic function of the quantities A_i defined by $A_i = k \mathbf{a}_i \cdot \mathbf{H}$; $i=1, 2, 3$ in which $k=2\pi/\lambda$ and $\mathbf{H}=\mathbf{s}-\mathbf{s}_0$. $\mathbf{a}_1, \mathbf{a}_2$ and \mathbf{a}_3 represent the three primitive vectors of the space lattice. In the case of fine powders the extinction effect is negligible⁵ and each unit cell of the crystal may be regarded as diffracting in the direction of \mathbf{s} rays which are identical except for phase. In the expression for the total intensity of the diffracted beam, A_1, A_2 , and A_3 represent the phase differences between rays diffracted by cells adjacent respectively along the three crystallographic axes of the crystal. The principal maxima of the function occur when the phase differences, A_i , are integral multiples of 2π , i.e. when $A_i=2\pi h_i$; $i=1, 2, 3$ in which the quantities h_i are integers. It will be noted that h_1, h_2 , and h_3 are respectively n times the Miller indices of the Bragg planes of the crystal where n is the order number.

In the cubic system, the magnitudes of the three vectors \mathbf{a}_i are equal and we can write $|\mathbf{a}_i|=a$. This makes it possible to regard A_1, A_2 , and A_3 as the projections on the three crystallographic axes of a vector, $\mathbf{A}=ka\mathbf{H}$. Consider a rectangular cartesian system in which A_1, A_2 , and A_3 are the coordinates with axes parallel to the crystallographic axes of the crystal. We will designate the space thus defined as A -space. Each point, A_i , of this space deter-

⁵ R. J. Havighurst, *Phys. Rev.* [2] **28**, 882 (1926).

mines a value of the intensity function. The points $2\pi h_i$ in A -space form a lattice which is geometrically similar to Ewald's reciprocal lattice.⁶ Each such point corresponds to a principal maximum of the diffraction pattern.

Since H is the difference of two unit vectors, s and s_0 , its numerical value is $2 \sin(\theta/2)$ in which θ is the angle between the two vectors, s and s_0 , i.e. the angle of diffraction. It follows that A , the numerical value of A , may be expressed by

$$A = ka |H| = (4\pi a/\lambda) \sin(\theta/2). \quad (2)$$

The direction of A is that of H and depends only upon the directions of the incident and diffracted rays. The vector A is therefore independent of the size, shape and orientation of the crystal. If the incident beam falls upon a crystalline powder, the same vector A pertains to the ray diffracted by each crystal in the direction determined by the angle θ . To each crystal of the powder there corresponds an A -space with axes parallel to the crystallographic axes of the crystal. The total intensity of the beam diffracted through the angle θ by the powder is the sum of the values of the intensities determined in the A -spaces of the several crystals by the vector, A .

The intensity function is determined by the size and shape of the crystal, the crystal lattice and the structure factor. Consider a large number, N , of crystals of uniform size, shape, space lattice and structure. Then the same intensity function, J , will pertain to the A -spaces of all the crystals and the total intensity will be found by integrating J between such limits as to include all possible orientations of the crystallographic axes. For the purpose of carrying out this integration, it is convenient to specify the orientation in terms of the direction of A_0 , the radius vector of the point $2\pi h_i$ in A -space corresponding to the diffraction maximum, h_i , with which we are concerned. Let ϕ be the polar angle between the directions of A and A_0 ; ξ , the azimuth angle about the direction of A as a pole; and ψ , that about the direction of A_0 as a pole. The total intensity, I , will then be represented by

$$\begin{aligned} I &= N \frac{\int_0^\pi \int_0^{2\pi} \int_0^{2\pi} J(A_i) \sin \phi \, d\phi \, d\xi \, d\psi}{\int_0^\pi \int_0^{2\pi} \int_0^{2\pi} \sin \phi \, d\phi \, d\xi \, d\psi} \\ &= \frac{N}{4\pi} \int_0^\pi \int_0^{2\pi} J(A_i) \sin \phi \, d\phi \, d\psi \end{aligned} \quad (3)$$

since $J(A_i)$ is invariant with respect to ξ . This double integral is the same as that representing the integral over the surface of the sphere in A -space whose center is the origin and whose radius is A . It will be convenient to consider I as this surface integral.

The intensity function⁴ for the case of a crystal whose shape is a cube with edges parallel to the crystallographic axes is well known. Expressed in terms

⁶ P. P. Ewald, *Zeits. f. Krist.* 56, 129 (1921).

of the intensity diffracted by one unit cell per unit solid angle in the specified direction, it is given by

$$J = \frac{\sin^2 \frac{1}{2} M A_1}{\sin^2 \frac{1}{2} A_1} \cdot \frac{\sin^2 \frac{1}{2} M A_2}{\sin^2 \frac{1}{2} A_2} \cdot \frac{\sin^2 \frac{1}{2} M A_3}{\sin^2 \frac{1}{2} A_3} \quad (4)$$

in which M is the number of unit cells along one edge of the cube. The principal maxima of J occur when $A_i = 2\pi h_i$ and the value of J at these maxima is $J_0 = M^3$. Because of its structure the intensity of the rays diffracted by a unit cell will vary with the direction thus causing the various principal maxima to have different intensities. In a study of the variation of intensity within a diffraction band, we compare the surface integrals over spheres in A -space which comprise a very thin spherical shell and we may neglect the variation of the structure factor with respect to A within this shell. This is accomplished by measuring the intensity function in terms of its maximum value at $A_i = 2\pi h_i$ for the band, h_i , under investigation and gives

$$J' = J/J_0. \quad (5)$$

Let us investigate the intensity function for an octahedron consisting of a simple cubic lattice with axes x, y, z along the diagonals of the octahedron and a single diffracting particle at each point of the lattice. Let M be the number of diffracting particles along a diagonal. We will take M to be an odd integer. We will specify the points of the lattice by the coordinate whole numbers n_1, n_2, n_3 measured parallel to the x, y, z axes respectively in terms of the length of the unit cell i.e. $x = n_1 a, y = n_2 a, z = n_3 a$. The points having a particular value of n_3 form a square parallel to the x, y plane whose diagonals extend from $-(m - |n_3|)$ to $(m - |n_3|)$ in which $m = 1/2 (M - 1)$. In this square the points having a particular value of n_2 form a row which extends from $n_1 = -n_1''$ to $n_1 = n_1''$ in which $n_1'' = m - |n_2| - |n_3|$. The resultant of the rays diffracted in the direction of s by the $(2n_1'' + 1)$ points comprising the n_2, n_3 row will be in phase with that diffracted in this direction by the central point, $0, n_2, n_3$, of the row. The contribution of any point, n_1, n_2, n_3 to this resultant is $\cos(n_1 A_1)$ multiplied by the amplitude. Measured in terms of the ray diffracted in the direction of s by any point, the resultant is $\sum_{-n_1}^{n_1} \cos(n_1 A_1)$. As we now proceed to combine the resultant rays from the various rows of the n_3 square, we are combining rays having unequal amplitudes whose values are symmetrically distributed about the central row, $0, n_3$. Each component ray has the phase of the central point of its row. The resultant will therefore have the same phase as that of the ray diffracted by the central point $0, 0, n_3$ of the n_3 square and will be

$$\sum_{-n_2'}^{n_2'} \{ \cos(n_2 A_2) \sum_{-n_1}^{n_1} \cos(n_1 A_1) \}$$

in which $n_2' = m - |n_3|$. Similarly we may combine the rays from all such squares and obtain P , the resultant amplitude of the ray diffracted by the octahedron in the direction of s .

$$P = \sum_{-m}^m \left\{ \cos(n_3 A_3) \sum_{-n_2'}^{n_2'} \left[\cos(n_2 A_2) \sum_{-n_1'}^{n_1'} \cos(n_1 A_1) \right] \right\}. \quad (6)$$

Principal maxima of P occur when $A_1 = 2\pi h_1$, $A_2 = 2\pi h_2$, $A_3 = 2\pi h_3$ where h_1 , h_2 , h_3 are integers. The value of these maxima is $P_0 = (4m^3 + 6m^2 + 8m + 3)/3$ and the intensity function measured in terms of the intensity at a maximum is $J' = P^2/P_0^2$. (7)

An investigation of the variation of P with respect to M shows that if P is expressed in terms of new variables, $u_i = 1/2 M(A_i - 2\pi h_i)$, it is approximately independent of M in the neighborhood of the point $2\pi h_i$. If we now write the expression for J_∞' , the limit of J' as M approaches ∞ , the summations of Eq. (6) become definite integrals which may be evaluated. The result of the integration is

$$J_\infty' = 6 \left\{ \frac{(u_1^2 - u_2^2)u_3 \sin u_3 + (u_2^2 - u_3^2)u_1 \sin u_1 + (u_3^2 - u_1^2)u_2 \sin u_2}{(u_1^2 - u_2^2)(u_2^2 - u_3^2)(u_3^2 - u_1^2)} \right\}. \quad (8)$$

An investigation of Eq. (8) shows that the distribution of the values of J_∞' about the origin of u_i is nearly spherical i.e. J_∞' is approximately a single valued function of $u = (u_1^2 + u_2^2 + u_3^2)^{1/2}$. For any given value of u , maxima or minima occur if (a) $u_j = u_k = 0$, (b) $u_i = u_j$, $u_k = 0$, or (c) $u_i = u_j = u_k$. On the sphere in A -space whose radius is u and whose center is $2\pi h_i$ these maxima and minima occur at intersections with diameters parallel respectively to (a) the axes of the space lattice, (b) the diagonals of squares bounding the unit cells, and (c) the diagonals of the unit cells. The values of J_∞' for these three conditions are given by

$$\left. \begin{aligned} \text{(a)} \quad J_\infty' &= \frac{6}{u_i^3} (u_i - \sin u_i), & u &= u_i \\ \text{(b)} \quad J_\infty' &= \frac{3}{u_i^3} (\sin u_i - u_i \cos u_i), & u &= \sqrt{2} u_i \\ \text{(c)} \quad J_\infty' &= \frac{3}{4u_i^3} [(1 + u_i^2) \sin u_i - u_i \cos u_i], & u &= \sqrt{3} u_i \end{aligned} \right\} \quad (9)$$

and are shown as functions of u in curves Ia, Ib, and Ic of Fig. 1. For values of $u > 5.7$, minima at which $J_\infty' = 0$ occur at other points on the sphere. It follows that when $u < 5.7$ all values of J_∞' must lie in the narrow strip enclosed between the curves and when $u > 5.7$, in that enclosed between the curves and the line $J_\infty' = 0$.

The nature of the approximation involved in using Eq. (8) instead of Eq. (7) is shown by curves Ia, Ib and Ic of Fig. 2. Here the corrections which must be applied to J_∞' in order to obtain the value of J' for the case, $M = 11$ are plotted against u . The correction curves for larger values of M are of the same general form with maxima and minima approximately at the same values of u , but they have smaller values for the ordinates. The correction for any

value of u is approximately inversely proportional to M^2 . For values of M which ordinarily occur these corrections are small.

The secondary maxima of the function J' defined by Eqs. (6) and (7), lie on the diagonals of the cubes of the lattice formed in A -space by the principal maxima points, $2\pi h_i$. At the centers of these cubes where three such diagonals intersect there occur secondary maxima at which the intensity is approximately three times that at the neighboring secondary maxima. The large ordinate at $u=29.9$ in curve Ic of Fig. 2 is due to such a large secondary maximum. In the derivation of Eq. (6), M was assumed to be odd. If M were even, no secondary maxima would occur at these points in A -space.

Fig. 1. The intensity function, J'_∞ , plotted against u ; (I), for octahedral crystals; (II), for cubical crystals. u is measured parallel to the radius vector A_0 of (a) the (1, 0, 0) maximum, (b) the (1, 1, 0) maximum, (c) the (1, 1, 1) maximum.

Substituting the coordinates of these points, $(2\pi h_i - \pi)$, for A_i in Eq. (6) we obtain $P = (-1)^m (3/M) (M^2 + 1) / (M^2 + 5)$ which gives a value of J approximately $9/M^2$ times that at the neighboring principal maxima. Colloidal crystals have been examined by x-rays⁷ for which the equivalent value of M was as small as 9. Crystals of this size, having octahedral shape and a simple cubic lattice would form an x-ray powder spectrogram in which these large secondary maxima should be directly observable as faint diffraction bands. The principal maxima points, $2\pi h_i$, form in A -space a simple cubic lattice, geometrically similar to the reciprocal lattice⁸ of the crystal. If we include the large secondary maxima points, $(2\pi h_i - \pi)$, the reciprocal lattice becomes body-centered. Since the reciprocal lattice of a face-centered crystal is a body-

centered lattice, the observed diffraction pattern would be similar to that of a face-centered crystal. The relative strengths of the bands would be very much like that observed in the diffraction pattern of sodium fluoride.

Fig. 2. The correction function, $G(M, u_i) = J' - J_\infty'$ plotted against u ; for a simple cubic lattice; (I) octahedral crystals, $M=11$; (II) cubical crystals, $M=6$. The small circles show corresponding values for a face-centered lattice. u is measured parallel to the radius vector A_0 of (a) the (1, 0, 0) maximum, (b) the (1, 1, 0) maximum, (c) the (1, 1, 1) maximum.

The intensity function in the case of a cubical crystal may be treated in the same way as in the case of an octahedral crystal. If we express J' of Eq. (5) in terms of u_i and take the limit as M approaches ∞ we obtain

$$J_\infty' = \frac{\sin^2 u_1}{u_1^2} \cdot \frac{\sin^2 u_2}{u_2^2} \cdot \frac{\sin^2 u_3}{u_3^2}. \quad (10)$$

The conditions for maxima and minima of this function are similar to those for Eq. (8). Curves IIa, IIb, and IIc of Fig. 1 show the corresponding maxima and minima as functions of u . In this case additional minima at which $J_\infty' = 0$ occur for values of $u > 3.3$. Curves IIa, IIb, and IIc of Fig. 2 show the corrections to be added to J_∞' to obtain the value of J' for the case, $M=6$. Here also the correction for a particular value of u is inversely proportional to M^2 .

Since crystals having face-centered lattices are of particular interest, the intensity functions have been developed also for diffracting particles at the points of a face-centered lattice. In the octahedral case, the result is

$$J' = \left[\frac{P+Q}{P_0+Q_0} \right]^2 \quad (11)$$

in which

$$Q = \sum_{-m+1}^{m-1} \left\{ \cos(n_3 A_3) \frac{1}{4} \sum_0^{n_2'-1} \left[\cos(n_2 A_2 + \frac{1}{2} A_2) \sum_0^{n_1''} \cos(n_1 A_1 + \frac{1}{2} A_1) \right] \right\}$$

⁷ R. Zsigmondy, "Kolloidchemie," Leipzig 1920, p. 406.

+ two other terms formed from the first by a rotation of subscripts and $Q_0 = 4m^3 + 6m^2 + 2m$. The limit of J' as M approaches ∞ is identical with J_∞' as given by Eq. (8). The corrections to be added to J_∞' to obtain J' are so small that the curves have not been drawn. The points indicated by the small circles in Fig. 2 indicate some of the values for $M = 11$.

In the case of crystals of cubical shape with a face-centered lattice

$$J' = \left(\frac{R+S}{R_0+S_0} \right)^2 \quad (12)$$

in which $R = J^{1/2}$ as given by Eq. (4), $R_0 = M^3$,

$$S = \frac{\sin \frac{1}{2}MA_1}{\sin \frac{1}{2}A_1} \cdot \frac{\sin \frac{1}{2}(M-1)A_2}{\sin \frac{1}{2}A_2} \cdot \frac{\sin \frac{1}{2}(M-1)A_3}{\sin \frac{1}{2}A_3}$$

+ two other terms formed from the first by rotation of subscripts and $S_0 = 3M(M-1)^2$. The limit of J' as M approaches ∞ is identical with J_∞' as given by Eq. (10). The corrections to be added to J_∞' to obtain J' are larger than in

Fig. 3. The correction function, $G(M, u) = J' - J_\infty'$ plotted against u for a face-centered lattice and cubic crystals, $M=10$. The small circles show corresponding values for a simple cubic lattice. u is measured parallel to the radius vector A_0 of (a) the (1, 0, 0) maximum, (b) the (1, 1, 0) maximum, (c) the (1, 1, 1) maximum.

the other cases studied. The curves are shown in Fig. 3 for $M=10$. As in the other cases the positions of the maxima of these curves vary but slightly with M . In this case the ordinates are approximately inversely proportional to M . For the purpose of comparison, corrections for the case of the cubical shape with a simple cubic lattice for $M=10$ are shown in Fig. 3 by small circles.

The narrow limits, between which all values of the intensity function must lie as shown in Fig. 1, make it possible to select an integrable function of u which closely approximates J . An approximate solution of our problem may be obtained by substituting this function for J in Eq. (3) and performing the integration. An investigation⁹ of the case of octahedral crystals by this

⁹ C. C. Murdock, Phys. Rev. [2] 31, 304 (1928).

method gave the value of the constant K of Eq. (1) as 1.6 when D was measured through the center of the octahedron from corner to corner. The investigation showed that the value of K was different for the various diffraction bands. The method of procedure, however, is not suitable for the study of this variation or for the determination of the form of a diffraction band.

Let us represent the function, J_{∞}' , by the expression, $e^{-u^2/p^2} + F(u_i)$ in which the value of p is so selected that the first term approximates J_{∞}' for the case under consideration. We may now express J of Eq. (3) as

$$J = J_0 J' = J_0 \{ J_{\infty}' + G(M, u_i) \} = J_0 \{ e^{-u^2/p^2} + F(u_i) + G(M, u_i) \} \quad (13)$$

in which $G(M, u_i)$ represents the correction to be added to J_{∞}' in order to obtain J' . The ordinates of Figs. 2 and 3 are values of G for the particular cases shown. We will use u^2 in place of ϕ as the variable of integration.

$$\begin{aligned} u^2 &= u_1^2 + u_2^2 + u_3^2 \\ &= \frac{1}{4} M^2 [A^2 + 4\pi^2 h^2 - 4\pi(h_1 A_1 + h_2 A_2 + h_3 A_3)] \\ &= \frac{1}{4} M^2 [A^2 + 4\pi^2 h^2 - 4\pi h A \cos \phi] \end{aligned}$$

in which $h^2 = h_1^2 + h_2^2 + h_3^2$. Therefore $d(u^2) = \pi h A M^2 \sin \phi d\phi$.

In terms of u^2 the limits of integration of Eq. (3) become v^2 and w^2 where $v = \frac{1}{2} M(A - 2\pi h)$ and $w = \frac{1}{2} M(A + 2\pi h)$. These limits are such that the integration may be considered as a surface integration over the surface of a sphere in A -space whose diameter is $2A$. In changing variables from A_i to u_i we shifted the origin to the point, $2\pi h_i$, associated with the diffraction band, h_i , with which we are concerned. We also changed the scale of the space by the factor $1/2 M$. In terms of the new scale, the diameter of the sphere of integration is $AM = w + v$. The diameter of the sphere which passes through the point $2\pi h_i$ is $2\pi h M = w - v$. The point $2\pi h_i$ is not the only point on the surface of this sphere at which a principal maximum of J occurs. For example on the sphere of integration for the (1, 1, 1) diffraction band there are eight points, $2\pi h_i$, corresponding to the following values of h_i ; 1, 1, 1; -1, 1, 1; 1, -1, 1; 1, 1, -1; 1, -1, -1; -1, 1, -1; -1, -1, 1; and -1, -1, -1. Let N' represent the number of such points. Since J is a periodic function of A_i , the integration indicated in Eq. (3) includes the values of J in the neighborhood of all these points and the contribution to the integral in the neighborhood of each point is identical. J_{∞}' is not a periodic function. It can approximate $J_0 J$ only in the neighborhood of the point, $2\pi h_i$. In its integration the limits should be fixed so as to include $1/N'$ times the area of the sphere and the integral should be multiplied by N' . It will not be found necessary to specify exactly the upper limit of this integration. Its order of magnitude may be ascertained by taking the upper limit of u^2 as r^2 , where r represents the radius of a circle whose area is $1/N'$ times the area of the sphere. Thus $\pi r^2 = 4\pi^2 h^2 M^2 / N'$ and $r^2 = 4\pi^2 M^2 h^2 / N'$. The value of h^2 / N' is $1/6$ for the (1, 0, 0) and the (1, 1, 0) diffraction bands, but has a larger value for each of the other bands. The upper limit of integration is therefore of the order of magnitude of $2/3 \pi^2 M^2$ or larger.

Making these substitutions in Eq. (3) we obtain

$$I = \frac{NN'J_0}{4\pi^2 h A M^2} \left[\int_{v^2}^{r^2} e^{-u^2/p^2} d(u^2) + \int_{v^2}^{r^2} f(u, v) d(u^2) + \int_{v^2}^{r^2} g(M, u, v) d(u^2) \right] \\ = \frac{NN'J_0}{4\pi^2 h A M^2} [U + V + W], \quad (14)$$

in which $f(u, v) = 1/2\pi \int_0^{2\pi} F(u_i) d\psi$, the average value of F with respect to ψ , $g(M, u, v) = 1/2\pi \int_0^{2\pi} G(M, u_i) d\psi$ and U , V , and W represent respectively the three integrals of the equation.

The first integral, U , of Eq. (14) has the same value for each band, h_i , and may be written

$$U = \int_{v^2}^{r^2} e^{-u^2/p^2} d(u^2) = p^2 e^{-v^2/p^2} \quad (15)$$

if r^2/p^2 is large. Since $r^2/p^2 \geq \frac{2}{3}\pi^2 M^2/p^2$ and M^2/p^2 is of the order of 10 for the smallest colloidal crystals so far studied,⁷ this assumption is justified.

The second integral, V , of Eq. (14) varies from band to band. It may be evaluated graphically by the following method. Contour plots are made of the function, $F(u_i) = J_\infty' - e^{-u^2/p^2}$ for a number of values of u . These may be made on the surfaces of spheres, the radii of which are taken as equal to u . It has been found more convenient, however, to make plots which are the projections of such spherical plots upon planes tangent to the sphere and perpendicular to the direction of the vector A_0 . From these plots the curves for $F(u_i)$ at various values of u and v are plotted as functions of ψ and integrated by inspection to obtain the values of $f(u, v)$. These values are then plotted as functions of u^2 for various values of v and the integrals evaluated graphically.

It is not practicable to carry out this process to the upper limit of integration. For large values of u , the value of f becomes small but remains finite and small errors in the function produce large errors in the integral due to the fact that the integration is performed with respect to the square of u . If s^2 is the upper limit of the graphical integration it leaves a part, $\int_{s^2}^{r^2} f(u, v) d(u^2)$, unevaluated. By properly choosing the value of s , the error involved in neglecting this part of the integral may be compensated in making the experimental observations. In an experiment the incident radiation will not be strictly monochromatic. Moreover there will be some generally scattered radiation. Both of these effects will give a background intensity superimposed upon that which we are computing. In practice the intensity is measured on either side of a diffraction band and from these data the background intensity is estimated for the points in the band on the assumption that there are no maxima or minima in the background intensity in that region. If the value of s is taken two or three times the largest value of v used, this assumption is also justified for $\int_{s^2}^{r^2} f(u, v) d(u^2)$ and the part of the intensity proportional to it will be automatically subtracted from the measured intensity as part of the background correction.

The third integral, W , of Eq. (14) may be evaluated by the method used for the evaluation of V . If, however, G can be approximated by an integrable function of u , it will be simpler to proceed as in the case of J_∞' . An examination of the correction curves of Figs. 2 and 3 shows that the (a), (b) and (c) curves of each set are practically identical for the smaller values of u and that for the larger values, two curves of each set have small ordinates. Advantage may be taken of this to approximate G by the function $Cu^2e^{-u^2/p^2}$ which gives as a first approximation

$$W = Cp^2(p^2 + v^2)e^{-v^2/p^2}. \quad (16)$$

C is a function of M . It may be expressed for the various cases studied as shown in Table I.

TABLE I.

	Cube	Octahedron
Simple lattice	$C = 1/(3M^2)$	$C = -1/(2M^2)$
Face-centered lattice	$C = 1/(3M)$	$C = 0$

The remainder, $G - Cu^2e^{-u^2/p^2}$, may now be integrated by the method described for the evaluation of V .

Since W depends upon M , which, in general, can only be known as a result of the solution of our problem, we will first investigate the case in which W is negligible. If $W = 0$, Eq. (14) may be written

$$I = \frac{NN'J_0L}{4\pi^2hAM^2}, \quad (17)$$

in which $L = U + V$. L is the surface integral over the sphere of $N'J_\infty'$. The only quantities in the second member of Eq. (17) which depend upon v , are L and A . If, therefore, we measure the intensity in terms of its maximum value, I_0 , for which $v = 0$, we obtain

$$I' = I/I_0 = L'A_0/A, \quad (18)$$

in which $L' = L/L_0$ and L_0 represents the value of L when $v = 0$. The factor A_0/A may be written by Eq. (2) as $\sin(\theta_0/2) \div \sin(\theta/2)$ in which θ_0 is the value of θ corresponding to the maximum, h_i . In this form it is seen to be determined by directly observable quantities. Within a diffraction band θ differs only slightly from θ_0 and the factor may be written $1/(1 + \frac{1}{2} \cot(\theta_0/2) \Delta\theta)$ where $\Delta\theta = \theta - \theta_0$. Since this factor is unsymmetrical with respect to $\Delta\theta$ it introduces asymmetry in the diffraction band. It is due to the fact that the integrations for values of v which are numerically equal but of opposite sign, are performed over spheres of different areas. In the graphical process for the evaluation of V another source of asymmetry occurs. It is due to the curvature of the spherical surface. No case has yet been found in which this second asymmetry is large enough to be taken into consideration. Because of the small value of

s used in the evaluation of V an integration in the spherical surface is practically the same as an integration in the tangent plane perpendicular to the vector, A_0 . If the integration is performed in this plane, the asymmetry due to curvature does not appear in the result.

We may now write Eq. (18) as

$$L' = [1 + \frac{1}{2} \cot(\theta_0/2) \Delta\theta] I'. \quad (19)$$

In this form there are collected in the second member the experimentally observable factors and the first member is a symmetrical function which may be computed for any band h_i from the integrals U and V of Eq. (14). U is the same for all bands. If V is integrated over the tangent plane it will vary from band to band due to the variation of the direction of the vector A_0 . This is, however, the same for all bands having the same Miller indices. It follows that the function L' will be the same for all orders of a diffraction band and need only be computed for one order.

The function L' has been computed for the (1, 0, 0), the (1, 1, 0), and the (1, 1, 1) diffraction bands in the cases of cubical and octahedral crystals. In the cubical case, the value of p was taken as $\sqrt{3}$, contour plots were made for eight values of u , and the graphical integration performed to the limit $s^2 = 90$. In the octahedral case the value of p was taken as 3, contour plots were made for eleven values of u , and the graphical integration performed to the limit $s^2 = 120$. Table II gives the resulting values of L' as determined. The uncertainty in the values due to the errors of the operation are of the order of ± 0.005 . Since L' is a symmetrical function the values are given for the positive values of v only.

TABLE II.

v	Cube L'			v	Octahedron L'		
	(1, 0, 0)	(1, 1, 0)	(1, 1, 1)		(1, 0, 0)	(1, 1, 0)	(1, 1, 1)
0	1.000	1.000	1.000	0	1.000	1.000	1.000
1	.728	.692	.680	1	.874	.891	.905
1.41	.500	.445	.466	2	.591	.631	.673
1.73	.333	.300	.333	2.6	.428	.456	.504
2	.221	.211	.268	3.2	.292	.305	.348
2.5	.074	.123	.170	4	.177	.145	.170
3	.027	.089	.131	5	.105	.060	.051
3.5			.094	6	.064	.046	.020
4	.054	.072	.069	7	.039	.040	.025

Experimentally we measure the width of a diffraction band in terms of differences in the angle of diffraction. By the definition of v , and by Eq. (2), we obtain

$$v = \frac{1}{2} M(A - 2\pi h) = (2\pi a M / \lambda) [\sin(\theta/2) - \sin(\theta_0/2)].$$

If we substitute $d/d\theta (\sin \theta/2) \Delta\theta$ for $\sin(\theta/2) - \sin(\theta_0/2)$ we obtain

$$v = (\pi a M / \lambda) \cos(\theta_0/2) \Delta\theta.$$

Let v' represent the value of v for which $I' = 1/2$ and, following Scherrer, let B represent the half intensity breadth of a diffraction band, measured in radians. Then

$$v' = (\pi a M / \lambda) \cos (\theta_0 / 2) (B / 2)$$

and

$$B = (2v' / \pi) \cdot \lambda / (Ma \cos (\theta_0 / 2)). \quad (20)$$

This is identical with Eq. (1) obtained by Scherrer since $Ma = D$, the length of the crystal along a crystallographic axis. Thus we obtain for the value of K , $2v' / \pi$. For comparing crystals of different shape, it is convenient to measure the size of the crystal in terms of D' , the cube root of the volume. D' may be used in place of D in Scherrer's equation, if a suitably modified constant K' is used in place of K . For the cubical shape $D' = D$ and $K' = K$. For the octahedral shape $D'^3 = 1/6 D^3$ and $K' = K/6^{1/3}$. Table III shows the values of v' , K and K' as computed from the data of Table II.

TABLE III.

Indices	Cube		Octahedron		
	v'	$K = K'$	v'	K	K'
(1, 0, 0)	1.41	0.90	2.32	1.48	0.81
(1, 1, 0)	1.32	0.84	2.45	1.56	0.86
(1, 1, 1)	1.36	0.87	2.62	1.67	0.92

These values are in general smaller than the results of previous investigations. Scherrer's value of K as computed from Eq. (1) is 0.94. Seljakow² obtained 0.92 and v. Laue³ 0.90 for the value of K for the cubical case. The previous investigation⁹ of the octahedral case gave $K = 1.6$ or $K' = 0.88$, a value 7 percent less than Scherrer's value of K . This difference was attributed to the shape of the crystal and it was concluded that the values of the crystal volumes which have been estimated by the use of Scherrer's equation were too large by 20 percent if the true shape of the crystals was octahedral. It now appears that the smaller value of K was due not so much to the shape of the crystals as to the method of computation. An examination of Table III shows that the mean values of K' in the cubical case and in the octahedral case are practically the same. Both Seljakow² and v. Laue³ used methods which may be regarded as the substitution of a function of u for the intensity function.

The results shown in Table III illustrate the dependence of the half intensity width of a diffraction band upon the indices of the band. The numerical order of the values of K in the two cases is different. In the cubical case the largest value of K is that of the (1, 0, 0) band while in the octahedral case it is that of the (1, 1, 1) band. In each case, the value of K for the diffraction band which is associated with a Bragg plane, parallel to a face of the crystal, is larger than the values which are associated with the other planes.

The shape of the crystals not only influences the relative width of the diffraction bands but also the form of the bands. This is shown in Fig. 4 in which

L' is plotted against v/v' , or what is the same thing, $2\Delta\theta/B$. On this scale the half intensity width of all the diffraction bands is 2 and their shapes can be directly compared.

The upper halves of all the curves are practically the same and are sufficiently approximated by the exponential relation $L' = e^{-(v/1.2v')^2}$ which is

Fig. 4. The (1, 0, 0) (n), the (1, 1, 0) (n) and the (1, 1, 1) (n) diffraction bands for, (I) octahedral crystals, (II) cubical crystals. The scales are such that the maximum intensity is 1 and the half intensity breadth is 2. The unbroken line shows the corresponding Gauss error curve.

plotted in unbroken lines in the figure. The lower halves of the curves show marked variations. Three types occur:

- (a) that illustrated by I(1, 1, 1) and II(1, 0, 0), falls slightly below the exponential curve to a minimum and then rises to a secondary maximum;
- (b) that illustrated by I(1, 1, 0) and II(1, 1, 0) follows the exponential curve until well below the half intensity point and then becomes nearly parallel to the v/v' axis;
- (c) that illustrated by I(1, 0, 0) and II(1, 1, 1) lies well above the exponential curve throughout the lower half of the curve and continues to approach the axis of v/v' to the limits of the computation.

There is a correlation between the type of curve and the Bragg plane associated with the diffraction band. Type (a) occurs when the Bragg plane is parallel to the faces of the crystal, the (1, 0, 0) for the cube and the (1, 1, 1) for the octahedron. These are the same bands which show large values of K .

Type (c) occurs when the Bragg planes are perpendicular to lines connecting opposite corners of the crystal, the (1, 1, 1) for the cube and the (1, 0, 0) for the octahedron. Type (b) occurs for the (1, 1, 0) band in both cases. In both the cube and the octahedron the (1, 1, 0) planes are perpendicular to lines connecting the centers of opposite edges of the crystal. The extension of this correlation to the case of crystals of dodecahedral shape would suggest that in this case the (1, 1, 0) diffraction band would be of type (a).

These results have been obtained by assuming that the third integral, W , of Eq. (14) was negligible. This will not be true if M is very small. By Eq. (20) and Table II we may now estimate the value of M and compute corrections to account for the finite value of W . If $W \neq 0$, we must write in place of L' of Eqs. (18) and (19), $(L + W)/(L_0 + W_0)$ in which W_0 is the value of W when $v = 0$.

If W is small compared with L_0 we may write $(L + W)/(L_0 + W_0) = L' + (W/L_0) - (W_0/L_0) L'$ and compute W by Eq. (16) taking $p^2 = (1.2v')^2 = L_0$. This gives for the correction to be applied to L' ,

$$\Delta L' = W/L_0 - (W_0/L_0)L' = Cv'^2 \{ (v/v')^2 e^{-v^2/p^2} - 1.2^2 (L' - e^{-v^2/p^2}) \}. \quad (21)$$

This may be readily computed. C is given in Table I; v' in Table II; v/v' are the abscissa of Fig. 4; and e^{-v^2/p^2} are the corresponding ordinates of the unbroken line curves of Fig. 4.

At the half intensity point, Eq. (21) reduces to $\Delta L' = \frac{1}{2} Cv'^2$. If we assume the slope at the half intensity point to be that of the unbroken line curve we obtain for the correction to be applied to v' ,

$$\Delta v' = 0.72 Cv'^3. \quad (22)$$

Thus v' may be corrected for the finite value of W by multiplying it by the factor $(1 + 0.72 Cv'^2) = (1 + 1.8 CK^2)$. Since K and K' are proportional to v' this same correction factor may be applied to them and also to the values of D and M as computed by Scherrer's equation.

Eqs. (8) and (10) have been derived for the face-centered, as well as for the simple lattice. They may be shown to hold for the body-centered lattice as well. It follows that J' , its integral, L , and the results shown in Tables II and III and Fig. (4) hold for any of these space lattices. However, the corrections to these results computed by Eqs. (21) and (22) vary with the space lattice. The corrections have been derived on the assumption that the diffracting material is concentrated at the points of the lattice. Actually these points are merely centers of space distributions of diffracting material. Since the corrections depend upon the distribution of diffracting material within the unit cell, a more exact determination of W than that given by Eq. (16) does not seem to be warranted by the assumptions.

It has been assumed throughout the discussion that the crystalline powder is made up of crystals of uniform size. In practice this assumption is frequently not justified. Any attempt to determine the size distribution from the x-ray diffraction pattern requires a knowledge of the theoretical form of

the band for the case of uniform size. Indeed it was this requirement which instigated this investigation. The closeness with which the form of the diffraction bands agrees with the Gauss error curve as shown in Fig. 4 makes it possible to assume this form for the purpose of estimating the distribution of particle size. The (1, 1, 0) band is particularly suitable for this purpose. It is hoped that studies of the form of the (1, 0, 0) and (1, 1, 1) bands together with studies of the relative width of the bands will lead to information as to the shape of the colloidal crystals in cases where there is approximate uniformity of shape.

The shape of the x-ray diffraction bands of a very fine uniform crystalline powder has been computed for the (1, 0, 0), (1, 1, 0) and (1, 1, 1) planes of cubical and octahedral crystals of the regular system. The results are shown in Fig. 4 plotted to such scales that the maximum ordinate is 1 and the half intensity breadth, 2. The coefficient K of Eq. (1) which relates the half intensity breadth of a band to the size of the crystal has been computed for each case. The values are shown in Table III. In comparing these theoretical results with experimental data, one must take care to comply with the following conditions.

- (a) The experimental data must be corrected for "background" radiation and instrumental errors.
- (b) The corrected data must be multiplied by the asymmetrical factor, $[1 + \frac{1}{2} \cot(\theta_0/2) \Delta\theta]$ of Eq. (19).
- (c) An approximate value of M should be computed by Eq. (20) and Table III.
- (d) The corrections to the ordinates of Fig. 4 may then be computed by Eq. (21) and Table I and the approximate value of M may be corrected by the factor $(1 + 1.8 CK^2)$.

I wish to express my thanks to Sir William Bragg and to the managers of the Royal Institution for putting at my disposal the facilities of the Davy-Faraday Laboratory where the work of this investigation was started. I wish also to acknowledge the valuable assistance of Miss M. A. Ewer who carried out a considerable part of the computations.

SPECTRAL PHENOMENA IN SPARK DISCHARGES

By J. W. BEAMS

ROUSS PHYSICAL LABORATORY, UNIVERSITY OF VIRGINIA

(Received November 29, 1929)

ABSTRACT

Two methods are described for measuring the differences in the time of appearance of the spectrum lines in sparks. The first is a refinement of the Kerr cell method previously used and a detailed description of its use is included. The criticisms of Gaviola of the method are shown not to apply. The second method makes use of a rapidly rotating mirror which either reflects the dispersed light of the spark to a photographic plate or the undispersed light to the slit of a spectrograph. In either case the position of the beginning of a line on the photographic plate gives its time of appearance. The method of Henriot and Hunguenard was used to rotate the mirror. Photographs of sparks are shown with the mirror rotating 1830 r. p. s. However, higher rotational speeds have been used. It is concluded that the Kerr cell method is superior for examining the air lines in the initial stages of the spark; while the rotating mirror method is better in studying the appearance and duration of the metallic lines which are not present in the very first stages of the spark discharge.

ALTHOUGH the electric spark in air has been the subject of a very large number of careful investigations, most of the mechanisms in the various stages of the discharge still remain obscure. This state of affairs probably results from the fact that the essential phenomena of the spark occur in such a short interval of time that the apparatus used in most cases failed to separate them into their component parts. However, during the last few years considerable progress has been made in the study of the various stages of the spark, due largely to the development of several methods of investigation that make it possible to study processes occurring in from 10^{-6} to 10^{-9} sec. It is the purpose of this paper to describe two independent methods of investigating the spark discharge and to record some of the results obtained.

When the sparking potential is first applied across a spark gap the discharge does not take place instantaneously, but a certain average time is required for the initiation of the discharge.¹ This time—usually called the time lag of the spark—is decreased by increasing the overvoltage and becomes in some cases of the order of magnitude of 10^{-8} sec.²

When once the discharge is initiated and the effective resistance across the gap starts falling, very little is definitely known of the process except

that the potential across the gap does not fall instantaneously to zero but decreases at a finite and measurable rate.³

If the light emanating from the spark in air during its initial stages is examined spectroscopically, it is found that all the spectrum lines do not appear simultaneously. In general the air lines appear first, followed by the spark lines of the metal with the metallic arc lines appearing last. Observations on these phenomena were first made by Schuster and Hemsalech,⁴ while they were studying the duration of lines in metallic sparks. Their method consisted essentially in projecting the spectrum on a rapidly moving photographic film and measuring the relative positions of the various parts of the lines. Other workers⁵ have observed the spark in a rotating mirror with similar results. The time resolving power of their methods, however, was not sufficient to give anything but rough qualitative results. Recently⁶ a method based upon the findings of Abraham and Lemoine⁷ that the Kerr effect in some liquids disappears very quickly after the electric field producing it is relaxed, has been successfully used to measure the order of appearance of spectrum lines in condensed discharges. By this method the values for the differences in the time of appearance of the various air lines themselves as well as the lines of a few metals were measured directly in terms of the velocity of light.⁸ Since that time the method has been considerably refined and the observations on the air lines repeated. These values have also been confirmed by a rotating mirror method within the limits of precision of the latter method.

The experimental arrangement, except for refinements and details, is essentially the same as that previously described. The method, however, has been recently questioned⁹ on the basis that oscillations of large amplitude should exist that would complicate the results.* Since in the work care was taken to investigate experimentally the magnitude of the oscillations present and, since the writer believes the method might find applications to other experiments, it will be described somewhat more in detail.

In Fig. 1 light from the spark *A*, made parallel by a lens *L*, plane polarized by a Nicol prism *N*₁, passes through a Kerr cell *K*, made by immersing two parallel metallic plates in CS₂, into a second Nicol prism *N*₂ crossed with

* Note: In the writer's opinion the questions raised by Gaviola (*loc. cit.*) and by L. V. Hamos [*Zeits. f. Physik* **52**, 549 (1928)] concerning the "electro-optical shutter" have been adequately investigated and reported [Beams and Lawrence, *Jour. Franklin Inst.* **206**, 169, (1928)]. The cause of the discrepancy in the values in the difference in the average lags of the Faraday effect as observed by Beams and Allison, [*Phys. Rev.* **29**, 161 (1927)] and Allison, [*Phys. Rev.* **30**, 66 (1927)], which Dr. Gaviola claims no attempt was made to explain, was investigated and discussed by Allison in the paper referred to and shown to be due to the effect of wave-length upon the lag.

respect to N_1 . If a potential is applied across the plates of K and the plane of polarization of the light makes an angle (45° in these experiments) other than zero or 90° with the lines of force, light can pass N_2 because of the double refraction in K .¹⁰ This double refraction produced in CS_2 by the electric field is called the Kerr effect. If μ_1 and μ_2 are the refractive indices for the

Fig. 1

two rays then their phase difference after passing through the Kerr cell K is $D = 2\pi l / \lambda (\mu_1 - \mu_2) = 2\pi B l E^2$, where λ is the wave-length of the light, B is a constant for a given substance, wave-length and temperature, l is the length of the light path through the liquid, and E is the electric field strength. The intensity of light passing N_2 is

$$I = A \sin^2 D/2 = A \sin^2 \pi B l E^2$$

where A is a constant. As a result, for comparatively small values of D (6° to 16°) as used in most of these experiments, the intensity of light passing N_2 varies approximately as the fourth power of the field strength.

If an electric potential is slowly applied across the spark gap A in air until the spark discharge takes place, it has been previously found that no light from the spark intense enough to be detected by the eye passes N_2 , provided the lead wires are not too long and are approximately the same length as the light path. The Kerr effect in K therefore effectively vanishes by the time that the light reaches the cell, or the light from the spark is too faint to be observed for a certain time after the beginning of the discharge. If, however, the lead wires from A to K were lengthened, the light path remaining fixed, light passes N_2 . When the light was examined spectroscopically it was found that the spectrum lines for any given substance appeared in a definite order which was not a function of their wave-length or of their intensity when measured over the entire duration of the spark.

Fig. 2 shows schematically the arrangement used to measure the time between the appearance of the lines directly in terms of the velocity of light. The arrangement in Fig. 1 is merely modified to allow the light to pass to a movable trihedral mirror system M_1 before entering the cell. The mirror system, designed by Professor L. G. Hoxton, returns a beam of light parallel but displaced. The three mirrors silvered on the front surface are mutually perpendicular and mounted on a steel frame which slides on a wooden track 23 meters in length. The optical system was adjusted (with Nicol prisms uncrossed) until the intensity of the light passing N_2 remained constant while the mirror system was moved throughout the length of its track.

¹⁰ Kerr, Phil. Mag. 1, 337 (1875); 8, 85 (1879).

The lead wires from A to K were either symmetrical and equal in length or one of the leads was removed and one side each of A and K grounded with short wires to high capacity grounds as shown in Fig. 2. The lead can be lengthened or shortened over the ranges being investigated by a sliding copper bar T . The inductance and capacity of both the lead wires and K were made as small and uniformly distributed as conveniently possible. In some of the experiments a resistance $R = (L/C)^{1/2}$ (app. 500 ohms),

Fig. 2

where L and C are the inductances and capacities per unit length of the wire, is attached across the open ends to prevent possible reflections of the initial transients; while a variable capacity C_1 (0.0005 to 0.005 microfarads) and variable resistance R_1 were used to change the conditions in the spark. The circuit containing C_1 is in a plane at right angles to the Kerr cell circuit to avoid unnecessary inductive coupling. The spark gap A was illuminated by a source of ultra-violet light H placed vertically over it and in

a direction at right angles to the direction in which the light of the spark is observed. This reduces the time lag and causes the spark to jump at approximately the same potential each time.

When the spark at *A* takes place, the potential across it does not fall to its low later value instantaneously.³ Some recent unpublished work done by Dr. L. B. Snoddy in this laboratory indicates that the exact rate of fall of potential is not completely independent of the circuital factors, as, for example, the rate at which energy is fed into the spark, but that under the conditions here used the potential probably falls to half value within the limits of 10^{-9} to 3×10^{-8} sec. Of the remainder of the potential-time curve very little is definitely known. The fall of potential travels along the lead wires at approximately the velocity of light and starts discharging *K* at a time equal to the length of lead wire divided by the velocity of light after the beginning of the fall of potential across *A*. Now since it is possible to reduce the capacity of *K* to a comparatively small value (4 cm) the rate of fall of potential across *K* follows roughly the rate of fall across *A* but at a definite time later.*

If the exact rate of fall of potential across *K* were definitely known, it would then be possible to compute the time of optical cut-off, since a possible lag in the Kerr effect of CS_2 is at least short enough to be here neglected.¹¹ Such computations show that the intensity of the light passing *N*₂ has dropped to $1/e$ of its value by the time that the potential across *K* falls to 0.77 of its original magnitude. The cell is therefore effectively closed before the potential across *K* drops to half value. If, then, the amplitude of oscillations in the Kerr cell does not exceed $1/2$ the initial potential, when once the cell closes, it does not again effectively re-open.

The fact that the amount of light passing *N*₂ after the first optical cut-off was too small to effect the results obtained could easily be tested experimentally. The lead wire from *A* to *K* was lengthened until one or two lines appeared in the field of view. Then as the mirror system *M*₁ was slowly moved backward increasing the optical path, the intensity of the lines showed no rapid decreases and, when once they disappeared, did not reappear while the light path was lengthened over 30 meters. This shows that there are no effective short oscillations. Oscillations of longer period were also tested for by placing a mirror rotating at 2000 revolutions per second behind the cell and observing the light flashes passing *N*₂. The rotating mirror could easily resolve less than 10^{-7} sec, yet the spark appeared when reflected from the mirror as a single sharp image.

It was very easy, however, to introduce oscillations large enough to cause trouble by adding inductance and capacity or by sufficiently lengthening the lead wire from *A* to *K*. In fact, with a cell of 4 cm capacity and about 16 meters of lead wire the oscillations become very troublesome, although

* Note: By carefully purifying the CS_2 smaller cells than 4 cm can be used without sacrificing intensity of light passing *N*₂ for as is well known the dielectric strength of CS_2 can be considerably increased by careful purification.

¹¹ Beams and Lawrence, Jour. Franklin Inst. 206, 169 (1928).

longer wires than this have been used successfully. When a low resistance (5.2 ohms) thermocouple galvanometer was placed in series with K and the lead wires lengthened, the readings of the galvanometer, which gave an indication of the magnitude of the oscillations present, increased relatively fast for the first 2 or 3 meters, then increased slowly as more wire was added. Similar observations were made with a wave meter having a vacuum tube voltmeter as an indicator, by means of which an estimate of the amplitude of the oscillations could be obtained. The frequency of course decreased with increase of wire path. A method making use of Lichtenberg figures¹² was also used to get the maximum potential that was applied across the cell after the initial field is relaxed. The method as used here is only approximate but it indicated that the potential never attained more than one half its original value over the wire path range used, at least in the investigation of the air lines.

The fact that the oscillations in K did not have an amplitude greater than one-half the initial potential of the spark might at first seem surprising, but when consideration is taken of the resistance in the spark in its initial stages, the high frequency resistance of the wires, corona losses, etc., this relatively large damping is to be expected. The resistance of the spark gap during its initial stages is not known, but it must fall from a very large value to a comparatively small one in less than the time required for the potential to drop to a low value. If then one-fourth the oscillation period of the Kerr cell circuit is of the same general order of magnitude as that of the time required for the resistance and potential to fall in the spark, the oscillation in the Kerr cell will be highly damped during a part of its first quarter of a period. As the lead wires are lengthened the inductance and capacity of the Kerr cell circuit are increased and hence the amplitude of oscillations, which occur after the initial transient has discharged the Kerr cell, is increased. An increase of lead wire also increases the period of the oscillations as was observed. If, therefore, very long leads are used, it is necessary to introduce resistance. The addition of resistance lengthens the time of optical cut-off, but in most of the work, especially when long leads are used, the cut-off can be slowed down considerably without the introduction of serious complications. The oscillating circuit containing C_1 and A can be changed over a fairly wide range without producing undesirable oscillations in K . This results from the fact that when once the potential across A falls to a low value and the air in the gap is ionized, it does not again rise to a value that, when applied across K , will cause an appreciable amount of light to pass N_2 . This condition holds, of course, only when the oscillations in C_1 , as in all these experiments, are rapid enough to prevent complete deionization in the gap between half oscillations. Also, since the circuit containing C_1 is not coupled to the circuit containing K except through the spark gap A , oscillations of amplitude large enough to give trouble should not be induced in K even for narrow bands of harmonics, as these, under the given conditions, have too little energy to be effective.

¹² P. O. Pedersen, K. Danske Vidensk. Selkab. 1, 11 (1919); 4, 7 (1922); 8, 10 (1929).

The light after leaving N_2 either is focused on the slit of a spectroscope so that the length of the spark is parallel to the slit, or else the image is examined by means of a direct vision prism. The direct vision prism resolves most of the lines without a slit because of the fact that the spark starts as a narrow thread and expands radially. The air lines appear the full length of the gap. Table I gives the time of appearance of the strong air lines (since it was necessary to use a spectrograph of large light-gathering power and

fairly wide slit, the members of the above groups of lines were not clearly resolved.) with respect to the first line that appears. The observations could be repeated with a precision of 3×10^{-9} sec. It will be noted that the order of appearance is not a function of intensity or of wave-length and therefore not the result of the electro-optical dispersion in K . This dispersion in double refraction should make the lines seem to appear in the order of increasing wave-length, but as previously pointed out, is too small to produce serious error under the experimental conditions. When the lead wires were lengthened, the spark lines of the metal appeared as points on the electrodes, followed in turn by the metallic arc lines. The fact that the metallic lines appear in the field of view as points introduces the greatest difficulty in determining the time of their appearance; in fact, some of the previous values for the metallic lines are perhaps somewhat in error due to this cause. Photometric measurements on the rate of increase of intensity of these metallic lines have been attempted but without much success. The rate of evaporation of the metal is apparently variable but a more serious difficulty arises because of the uncertainties of the photographic plate when illuminated with light flashes of short duration.¹⁴ The Clayden effect and other effects that are probably related to it make practically all photographic measurements of light intensities with flashes as short as 5×10^{-8} sec. very unreliable. For example, if a photographic plate is slightly fogged by a weak light as is sometimes done to photograph faint sources of light¹⁵

¹³ Fowler and Freeman, Proc. Roy. Soc. A114, 662 (1927).

¹⁴ R. W. Wood, Astrophys. J. 17, 361 (1903). Lüppo-Cramer Grundlagen d. Photographischen Negativverfahren Halle 1, 608 (1927).

and then illuminated with a short flash, the image of the flash on the plate is usually reversed. Even when the plate is exposed to the flash alone and care is taken to prevent, as far as possible, fogging by other light, any developer fog is reversed. The intensity of the light is always a factor; a

A. Mg gap. = 7 mm

B. Bi gap = 8 mm

C. Bi gap = 8 mm

D. Bi

Fig. 3

faint flash produces a reversal, while a more intense flash gives the ordinary image with usually a reversal around its edges. Attempts have been made to eliminate these troubles but, in the case of flashes less than 5×10^{-8} sec. in duration without much success.

Because of these difficulties with the Kerr cell method when used for observing the metallic lines, as well as the fact that its precision decreases in

the later stages of the spark, a search has been recently made for an independent and complementary method of study. The method finally adopted has been made possible by the development by Henriot and Hunguenard¹⁶ of a means of obtaining high rotational speeds. A mirror 12×12 mm is mounted on a cone shaped piece of metal which rides on a whirling cushion of air. With this arrangement the angular speed is in general limited only by the viscosity of the gas, its molecular velocity and the strength of the rotating parts.

The light from the spark passes through a lens, is reflected by a rotating mirror and falls upon a photographic plate placed at the focus of the lens. Fig. 3, A. B. C. give traces of the image of a spark between magnesium electrodes and bismuth electrodes, each moving 1,300,000 cm/sec. perpendicular to its length. In each case the constants of the circuit are the same. It will be specially noted that the spark first appears as a bright streak completely across the gap. This bright streak fades out very quickly, but the luminosity persists near the electrodes and gradually moves toward the center of the gap. The visible spectrum of the bright streak is composed of air lines and that of the luminous streamers emanating from the electrodes, metallic lines. In the bismuth spark the curved metallic streamers which start from the cathode each half oscillation and move with diminishing velocity until they reach the moving vapor front are very distinct on the original plate. These streamers have been previously observed by several experimenters,⁵ but whether they are jets of luminous vapor or pulses of luminosity in the vapor has not yet been completely settled.

Fig. 3 D shows the image of the spark moving parallel to its length. A narrow portion is isolated by a slit perpendicular to the spark to prevent overlapping errors. It will be noted that the spark starts as a thread and expands radially. When the slit was removed or moved to allow only the light from near and including that on the surface of the electrode to reach the plate, and the light dispersed by a prism just before reaching the rotating mirror, the time of appearance of the various spectrum lines could be observed. Similar observations were made when the moving image of the spark fell upon the slit of a spectrograph. The photographs show plainly that the air lines appear first, followed by the spark and later by the arc lines. The technique, however, is not yet developed to a stage where the members of the metallic arc triplets can be distinctly separated, due probably to the photographic errors previously discussed. The limiting factor here seems to be intensity and not angular speed because it is not especially difficult to obtain rotational speeds of 4000 r. p. s. and this can be multiplied several times by simply allowing the light to be reflected from stationary mirrors back to the rotating mirror again. The work, however, is being continued with a better arrangement than that previously used.

The above experiments together with those performed by other investigators^{5,17} show definitely that the various spectrum lines in the spark appear

¹⁶ Henriot and Hunguenard, *Jour. d. Phys. et Ra.* 8, 443 (1927).

¹⁷ Locher, *J.O.S.A.* 17, 91 (1928).

at different times after the beginning of the discharge where by the appearance of a line is meant the time required for the line to become visible through the observing apparatus. However, there is a disagreement in the values obtained by Locher and the writer using similar methods. The difference perhaps lies partly in the larger Kerr cell used by Locher, which would lengthen the time for his cell to cut off. This probably explains, in part at least, why he could not completely extinguish the air lines with lead wires of the same length as his light path, for the intensity of the light passing his cell at maximum voltage was considerably less than that used by the writer so that any errors due to light intensity are in the wrong direction to explain the difference. He also had no way of slowly varying his light path which has been found essential in the above work in testing for troublesome oscillations, or of measuring his time directly in terms of the velocity of light.

The principal factors that determine the appearance of a spectrum line during the initial stages of a spark discharge through a gas must be the average time required to put the atom in the properly excited state by the discharge, the average time it remains excited, and the rate with which it radiates energy when once it starts radiating. In the case of the air lines the sum of the last two factors would be expected from the general results of canal ray experiments¹⁸ to be of the right order of magnitude to explain the observed time between the appearance of the groups of nitrogen lines. This then suggests that in the first stages of the discharge through air where a large number of atoms must be ionized before the potential can fall to a value which will effectively close the cell, that there is a correspondingly large number of atoms multiply ionized and excited to the upper energy levels of the strong air lines. Also, the distribution of excited atoms among the various upper levels of the strong lines probably does not change during the initial stages of the spark. It is possible to study the effect that the average time an atom holds its energy has upon the appearance of spectrum lines in the case of the arc triplets of zinc and cadmium. These triplets have the same upper energy level and therefore should be independent of the conditions of excitation in the discharge. In previous work⁷ these lines were found to appear at different times but it has not yet been possible to increase the time-resolving power of the rotating mirror method to a point where a difference in the time of appearance of the lines can be observed. This is necessary before definite conclusions should be drawn because it will then be possible to change the excitation conditions over a very much wider range than was possible with the Kerr cell method and thus make certain any possible effect of the discharge.

The writer is indebted to Professors L. G. Hoxton and C. M. Sparrow of this Laboratory and to Professor E. O. Lawrence of the University of California for many valuable criticisms of part of the work. He is also very grateful to Mr. A. J. Weed, instrument maker, for help in the construction of apparatus.

VIBRATIONAL QUANTUM ANALYSIS AND ISOTOPE EFFECT FOR THE LEAD OXIDE BAND SPECTRA*

BY SIDNEY BLOOMENTHAL

RESEARCH DEPARTMENT, RADIO CORPORATION OF AMERICA, NEW YORK CITY†

(Received November 19, 1929)

ABSTRACT

Each strong line (Pb^{206}O) in the band spectrum emitted by a uranium lead arc in air is represented by three lines ($\text{Pb}^{208}, ^{207}, ^{206}\text{O}$ with relative intensities in agreement with Aston) in the band spectrum from an ordinary lead arc. The first and second orders of a 21 ft. Rowland grating were used to make this comparison. The observed separations between corresponding band lines of isotopic molecules are in good agreement with the theory of the isotope effect in band spectra with PbO as the emitter.

New measurements of the wave-lengths of the band heads were made from moderate dispersion spectrograms of the ordinary lead arc in air. The bands in the near ultra-violet form a new system**

$$\nu = 30,197.0 + [530.6(\nu' + \frac{1}{2}) - 1.05(\nu' + \frac{1}{2})^2] - [722.3(\nu'' + \frac{1}{2}) - 3.73(\nu'' + \frac{1}{2})^2].$$

Three other systems in the visible have been discussed already by Mecke. Evidence in favor of combining two of these systems (*C* and *B*) into one is presented. All of the band systems have a common lower state.

INTRODUCTION

THE lead arc in air gives a fairly bright band spectrum consisting of a large number of heads all degrading towards longer wave-lengths. The same spectrum appears with compounds of lead subjected to a variety of conditions of excitation, and consequently there has been a great deal of speculation concerning the identity of the emitter.¹ Using low and moderate dispersion, Eder and Valenta² photographed the bands excited upon the introduction of lead chloride into an oxygen illuminating gas flame. They gave wave-length measurements of the heads to four figures, and believed that lead oxide was the emitter. Using the same method of excitation, Lamprecht³ photographed the visible region at moderate dispersion, and in addition the yellow green region at high dispersion, failing however to resolve the fine structure completely.

Grebe and Konen⁴ photographed the spectrum of a carbon arc containing ordinary lead chloride at high dispersion, and repeated using uranium lead

chloride. They limited themselves to a narrow region in the blue and found that the isotope effect was evident only as a slight wave-length shift and difference in the degree of sharpness of the band spectrum lines compared.

The first part of the present work deals with the vibrational quantum analysis of the lead oxide bands. New measurements of the wave-lengths of the band heads, believed to be more accurate than existing data, are used for most of this analysis. The isotope effect served to guide this part of the work.

In the second part the observed isotope effects will be discussed in detail, and it will be shown that the comparison of the single lines from uranium lead (Pb^{206}O) with the corresponding lines in the triplets $\text{Pb}^{208}, ^{207}, ^{206}\text{O}$ from ordinary lead is in quantitative agreement with the fact that ordinary lead contains isotopes 208, 207, 206.⁵ This comparison furnishes a direct test of the theory of the isotope effect in band spectra.

While this work was in progress, and after preliminary reports on the isotope effect had been issued,⁶ a short paper by Mecke⁷ appeared dealing with his independent work based on Lamprecht's data, leading to a vibrational quantum analysis. These data are not quite complete since Lamprecht gives no measurements of the bands in the red and near ultra-violet. Further details of Mecke's work will be taken up later.

EXPERIMENTAL PROCEDURE

Measurements were made from moderate dispersion spectrograms of the ordinary lead arc in air. In addition comparisons and measurements were made from high dispersion spectrograms in the study of the band structure and isotope effect, and these spectra were taken first with an ordinary lead arc and then with a uranium lead arc. The uranium lead used originated in Belgian Congo ores, and had an atomic weight of 206.1.

The arc electrodes were copper rods $\frac{1}{2}$ " in diameter. A bead of a molten alloy of copper and lead was formed on both the upper (—) and lower (+) electrodes while the arc was in progress by melting pure thin copper wire and lead filings. With the proper proportions of lead and copper in each of the two beads, the arc had a blue color and emitted the lead oxide bands in a satisfactory manner. Fresh lead filings were added at intervals of several hours to prevent the appearance of the green tinge denoting strong emission of the copper spectrum. Copper lines were present on the spectrograms but did not interfere seriously with the work. The red copper oxide bands, generally recorded in a few minutes when the copper arc itself is used, were weak or entirely absent. The current carried was three amperes supplied at 220 volts with a suitable series resistance.

Spectrograms were taken with the Hilger Littrow-mounted E1 prism spectrograph, having a dispersion with the glass optical system of approximately 21A/mm at 6500A to 6A/mm at 4400A, and with the quartz system of 14A/mm at 4200A to 5.8A/mm at 3200A. The resolution of the structure

lines is incomplete and the heads are single and fairly sharp except where overlapping is great. Exposure of one hour sufficed with the E1.

The high dispersion work was done in the first and second orders of the six inch 21 ft. Rowland concave grating having about 14,500 lines per inch and set up in a Rowland mounting. The dispersion in the first order is about 2.63A/mm. The exposure time was usually in excess of 15 hours. Fine grained plates were used in most of the photographic work. Iron lines were placed on the plates before and after exposure. Shifts due to temperature changes were minimized by an efficient system of temperature control consisting of thermostat, fan and heating unit with a mercury current break actuated by a sensitive relay circuit.

Reductions of the measurements of the moderate dispersion plates were made using the Hartmann⁸ formula and an automatic Monroe calculating machine. The residuals were small, generally of the order of 0.02A. The formula was applied to only about 200A of the plates at any one time. Kayser's "Schwingungszahlen" served to convert the corrected measurements to vacuum wave-numbers. The iron line wave-lengths selected by the International Astronomical Union served as standards⁹ in most of the reductions.

VIBRATIONAL QUANTUM ANALYSIS

In making the assignment of v values the new data on band head wave-lengths, which are believed to be better than the older data, were used. These were supplemented, however, where necessary by older values. This assignment is in agreement with the observed isotope effects (to be described later) using half integral values for the vibrational quantum number following Mulliken,¹⁰ who first found them necessary in the analysis of the BO band spectra. The suggestions of Birge¹¹ proved useful in evaluating the constants in the empirical frequency equations by means of a consideration of the first and second differences of the wave-numbers in the usual two dimensional matrix diagram.

Assuming that the head is close to the band origin, where the change in rotational energy is approximately zero, one employs the following formula for the frequency of a band head

$$\nu = \nu^0 + \omega_e'(v' + \frac{1}{2}) - x'\omega_e'(v' + \frac{1}{2})^2 + \omega_e''(v'' + \frac{1}{2}) - x''\omega_e''(v'' + \frac{1}{2})^2$$

where ω_e is the frequency of vibration for infinitesimal amplitude and v is the vibration quantum number which takes integral values 0, 1, 2,.... Primes (') and double primes (') refer, respectively, to the quantity indicated in the upper and lower electronic states.

Mecke assigned the bands in the wave-length region covered by Lamprecht's data to three systems A , B and C . The bands of the C system were extremely weak on the plates taken by the writer, and hence no measure-

ments were made on such heads. The writer has found an additional system *D* in the region 3209—3594Å which was not photographed by Lamprecht. The band head data and vibrational quantum assignments for the *A*, *B* and *D* systems are given in Tables I, II and III.

The data apply to band heads. In the case of PbO the origin of each band as shown by the results of the following paper lies close to the head. *I* is the relative photographic intensity of the band as a whole, λ the wave-length in air in international Angstroms and ν the vacuum wave-number. *O-C* is the difference between the observed wave-number and the value calculated from the proper empirical formulas given below. Under remarks brackets [] denote masking by a band of higher frequency whose ν values are enclosed. In some cases of masking it was not possible to secure the measurement of a head and the value of the wave-number calculated from the appropriate empirical formula is given in brackets. In such instances the relative intensity estimate was made from the plate enlargement, although the head was not measured. In cases where a measured wave-number value is classified in two systems, evidence justifying this has been found in extensive overlapping of the fine structure examined at high dispersion. The wave-number data for systems *A*, *B* and *D* are from new measurements.

When the suitable ν' and ν'' values are inserted, the following formulas give the wave-number of a classified band head to within a small difference from the measured value.

For heads in system *A*

$$\nu = 19,863.3 + [451.7(\nu' + \frac{1}{2}) - 3.33(\nu' + \frac{1}{2})^2] - [722.3(\nu'' - \frac{1}{2}) - 3.73(\nu'' + \frac{1}{2})^2]$$

For heads in system *B*

$$\nu = 22,289.8 + [496.3(\nu' + \frac{1}{2}) - 2.33(\nu' + \frac{1}{2})^2] - [722.3(\nu'' + \frac{1}{2}) - 3.73(\nu'' + \frac{1}{2})^2]$$

For heads in system *D*

$$\nu = 30,197.0 + [530.6(\nu' + \frac{1}{2}) - 1.05(\nu' + \frac{1}{2})^2] - [722.3(\nu'' + \frac{1}{2}) - 3.73(\nu'' + \frac{1}{2})^2]$$

Because of the fact that the isotope effect is unresolved at moderate dispersion, the constants given in these formulas are but approximations.

It is evident from inspection of these equations that all three systems have a common final state, which is probably the normal state of the PbO molecule. The systems *A*, *B* and *D* arise then from transitions from 2.5, 2.8, and 3.7 volt electronic levels, respectively, to this common lower state.

Mecke's equations based on Lamprecht's data are

$$(A) \quad \nu = 19,877 + [445(\nu' + \frac{1}{2}) - 1(\nu' + \frac{1}{2})^2] - [722(\nu'' + \frac{1}{2}) - 3.5(\nu'' + \frac{1}{2})^2]$$

$$(B) \quad \nu = 22,293 + [498(\nu' + \frac{1}{2}) - 1.4(\nu' + \frac{1}{2})^2] - [722(\nu'' + \frac{1}{2}) - 3.5(\nu'' + \frac{1}{2})^2]$$

$$(C) \quad \nu = 24,875 + [537(\nu' + \frac{1}{2}) - 15(\nu' + \frac{1}{2})^2] - [722(\nu'' + \frac{1}{2}) - 3.5(\nu'' + \frac{1}{2})^2]$$

System *D* is missing from Mecke's analysis since Lamprecht failed to secure wave-number data below 3740Å. Although the new equations of *A* and *B* are similar numerically to Mecke's, the writer believes that his equations

TABLE I. The A bands. New data and vibrational quantum analysis.

^a The intensity data of Table I for system B comes from Lamprecht's data. [A] denotes masking by A heads. These superposed bands are unusually strong in some cases.

plates taken by the writer. On the other hand, Lamprecht's data do not extend beyond 3740Å where the heads of the *D* system occur. Thus the older data in this region cannot be corrected to conform to the measurements made by the writer. Employing, therefore, Lamprecht's data for all the heads of

the bands in this region an equation for the *B* system is found including practically all of the heads of system *C*.¹² The equation is

$$\nu = 22,292 + [495.7(v' + \frac{1}{2}) - 2.05(v' + \frac{1}{2})^2] - [722.3(v'' + \frac{1}{2}) - 3.73(v'' + \frac{1}{2})^2]$$

The observed minus calculated values obtained from this equation are well within the experimental error of the measurements given by Lamprecht. It is obvious that this equation differs but little from the equation for the *B* system

^g The relative intensity estimates for Eder and Valenta's data were made by the writer from an examination of the PbO spectra in the Atlas.

^h These unidentified heads cannot be accounted for even if Mecke's system *C* is included with the other three systems. Many of these heads represent, no doubt, the superposition of a number of lines.

based upon the new data. However, until new data are obtained one may reasonably assume that thus far only three systems are known to be present in the spectrum of PbO, namely *A*, *B*, and *D*.

Table I illustrates the experimental intensity data. Comparison with the Franck-Condon theory is postponed until a fine structure analysis yields further data concerning the molecular constants of PbO.

BAND STRUCTURE AND ISOTOPE EFFECT

Under high dispersion each band consists apparently only of a *P* and *R* branch, which run coincident near the head of each band. Because of the fine

¹² The heads not included in *B* are 4281.2A, 4156.3A and 4036.2A.

scale of the band structure and overlapping of series, it is difficult to make accurate measurements of the wave-lengths of the individual lines. The bands in the red, yellow and green, photographed already at high dispersion with the uranium lead arc as source, appear to offer the best possibilities for a fine structure analysis. Such an analysis has been made already for some of the bands, and the results are given in a subsequent paper in collaboration with Dr. A. Christy.

The expression for the separation in wave-numbers between the corresponding band spectrum lines of two isotopic diatomic molecules¹³ is

$$\nu_2 - \nu_1 = (\rho - 1) \left[(v' + \frac{1}{2}) w_{e1}' - (v'' + \frac{1}{2}) w_{e1}'' \right] - (\rho^2 - 1) \left[(v' + \frac{1}{2})^2 x_1' w_{e1}' - (v'' + \frac{1}{2})^2 x_1'' w_{e1}'' \right] - (\rho^2 - 1)(\nu_1 - \nu_{Hd})$$

where $\rho = (\mu_1/\mu_2)^{1/2}$ and $\mu_1 = m_1 m / m_1 + m$, $\mu_2 = m_2 m / m_2 + m$. m_1 and m_2 are the masses of the isotopic atoms and m is the mass of the common kind of atom in the molecules $m_1 m$ and $m_2 m$. Subscript 1 refers to the constant for the more abundant and subscript 2 to that for the less abundant molecule. In our case m_1 is the mass of Pb^{208} , and m_2 the mass of Pb^{207} . For convenience one can make the following abbreviations.

$$\begin{aligned} \Omega &= (\rho - 1) \left[(v' + \frac{1}{2}) w_{e1}' - (v'' + \frac{1}{2}) w_{e1}'' \right] \\ O &= -(\rho^2 - 1) \left[(v' + \frac{1}{2})^2 x_1' w_{e1}' - (v'' + \frac{1}{2})^2 x_1'' w_{e1}'' \right] \\ \tau &= (\rho^2 - 1)(\nu_1 - \nu_{Hd}). \end{aligned}$$

The subscript 1 is dropped above since the isotope effect is unresolved at moderate dispersion.

$$\nu_2 - \nu_1 = \Omega + O + \tau.$$

Neglecting the rotational contribution τ and also the term O , the approximate magnitude of the (vibrational) isotope effect can be calculated simply by the relation

$$\nu_2 - \nu_1 = (\rho - 1)(\nu - \nu^0)$$

where ν^0 is the wave-number of the band system origin. ρ for PbO is $[(208 \times 16)(207 + 16)/(208 + 16)(207 \times 16)]^{1/2} = 1.000173$. This is approximately equal to $[(207 \times 16)(206 + 16)/(207 + 16)(206 \times 16)]^{1/2}$. Hence in the A system where $\nu^0 = 19,863.3$ and ν for the head of the 0,5 band is 16,227.9, then $\nu_2 - \nu_1 = -0.63 \text{ cm}^{-1}$. This is close to the observed value -0.68 ± 0.05 determined by direct comparison of the lines $Pb^{206}O$ from uranium lead with the lines $Pb^{208, 207, 206} O$ from ordinary lead. If Pb_2 were the emitter, then

$$\rho = [(208 \times 207)(207 + 207)/(208 + 207)(207 \times 207)]^{1/2} = 1.0015,$$

and the isotope separation $\nu_2 - \nu_1$ for the 0,5A band ought to be about 5.5 wave-numbers, almost nine times as large as the value actually observed.

¹³ R. S. Mulliken, Phys. Rev. 25, 119 (1925) and F. W. Loomis, Nat. Res. Council Bulletin 57, 11, 123 (1926). The last term in this formula is only an approximation.

Figure 1 illustrates the isotope effect observed near the head of the $\lambda 5677.78\text{\AA}$ (0,3A) band. The upper microphotometer record was secured from a spectrogram taken with uranium lead of atomic weight 206.1 in the arc. Below is the record of the same region on a spectrogram taken with ordinary lead (atomic weight 207.2) in the arc. A Moll microphotometer, which records automatically was used. The central reference line is a lead arc line of wave-length 5692.329\AA which probably shows a small atomic isotopic effect. The light vertical lines serve to identify the corresponding

Fig. 1. Isotope effect in the $\lambda 5677.78$ (0,3 A) band of PbO. Above, Pb^{206}O from uranium lead. Below, $\text{Pb}^{208}, ^{207}, ^{206}\text{O}$ from ordinary lead. Isotopic displacement -0.428 wave-numbers.

lines in the two spectra, namely Pb^{206}O . The lines Pb^{208}O and Pb^{207}O are apparently absent from the upper trace. Isotope 208 is the most abundant in ordinary lead, and hence Pb^{208}O gives the strongest lines. Aston gives 208 (7), 207 (3), and 206 (4) as the composition of ordinary lead, and the results of this investigation are in agreement with these relative abundancies. The wave-lengths of the series lines are given in the lower part of the figure.

Figure 2 gives a similar comparison near the head of the $\lambda 6160.52\text{\AA}$ (0,5A) band. Just as in the case of the 0,3 band, the lines Pb^{206}O are on the long wave-length side of the lines Pb^{207}O . The *P* and *R* lines are coincident

in the middle of the picture and begin to diverge both on the far left and far right side, causing the lines to become fuzzy. The single lines Pb^{206}O in the upper spectrum were secured with a heavy exposure in order to bring out weak lines of other isotopic molecules that might possibly be present. This was done in an attempt to satisfy Dr. C. S. Piggot's¹⁴ wish for a reliable qualitative analysis of uranium lead from the Belgian Congo. Data of this

Fig. 2. Isotope effect in the $\lambda 6160.52\text{A}$ (0,5 A) band of PbO .

nature are necessary in estimating the age of uranium minerals. It is evident from inspection of Fig. 2 that 206 is the principal isotope in the uranium lead sample used. This is to be expected from its atomic weight of 206.1.

Table V gives the measured wave-lengths of the band lines examined in Fig. 2. The first order of the grating was used. The numbers above the lines Pb^{206}O in Fig. 2 correspond to those under "group" in Table V.

TABLE V. Wave-lengths of lines in the 6160.52 A (0,5A) band.

Figure 3 illustrates the isotope effect observed in one of the *D* system bands. The band lines in the upper half of the figure are the lines Pb^{206}O from uranium lead. These are shifted $0.036 \pm 0.01\text{A}$ on an average approximately to longer wave-lengths with respect to the lower lines $\text{Pb}^{208, 207, 206}\text{O}$ from

¹⁴ C. S. Piggot, Jour. Wash. Acad. of Sciences 18, 10, 269 (1928).

ordinary lead, which are unresolved in this region. Table VI gives the wave-length data. These begin, reading from right to left, with the second line on the short wave-length side of the reference line in Fig. 4. It is to be noted that here the isotope effect is unresolved although the second order of the grating was used. This is in marked contrast to the effects observed in system *A*, but is in agreement with the shift calculated on the basis of the vi-

Fig. 3. Isotope effect in the $\lambda 3485.68\text{\AA}$ ($0,2 D$) band of PbO. Upper spectrogram, uranium lead oxide. Lower spectrogram, ordinary lead oxide.

brational assignment for the *D* bands. The calculated shift is -0.271 cm^{-1} for Pb^{208}O as compared with Pb^{207}O while the value measured is $-0.30 \pm 0.08\text{ cm}^{-1}$. The minus sign indicates that the lines from the molecules containing the lighter isotope are displaced towards lower frequencies with respect to the radiations from the molecules containing the heavier isotope.

Table VII gives a comparison between the observed isotope effects and the values calculated as the sum $\Omega + O + \tau$.

In the 0,3 band of system *A* the lines which we now recognize as Pb^{208}O and Pb^{206}O were measured by Lamprecht in 1911, who designated them as lines of series I and III in his tables of wave-lengths. The lines Pb^{207}O , which form the intermediate series, are missing from the data of Lamprecht, since he used lower dispersion and resolving power than did the writer.

TABLE VII. Isotope effects observed by direct comparison of Pb^{206}O from uranium lead with $\text{Pb}^{206,207,208}\text{O}$ from ordinary lead, and the values calculated as the sum $\Omega + O + \tau$.*

* The isotope effect calculated here is that of Pb^{208}O and Pb^{207}O and is approximately the same as that of Pb^{208}O and Pb^{207}O numerically.

Dr. R. S. Mulliken suggested this problem and gave a good deal of important advice in the course of this investigation. Consequently the writer takes this opportunity to thank him. To Drs. Gale, Compton, Harkins, Piggot, Hoag and Christy, the writer feels indebted for many helpful hints. The uranium lead of atomic weight 206.1 was a gift from the Wolcott Gibbs Memorial Laboratory of Harvard University, and the writer is indebted through Dr. Mulliken to Dr. L. P. Hall for making about 20 grams of pure material extracted from Belgian Congo uranium ores available.

When Dr. Mecke was informed of the present investigation, he very kindly agreed to leave further work on the fine structure analysis to the writer.

FINE STRUCTURE ANALYSIS OF THE BANDS IN
THE A AND D SYSTEMS OF LEAD OXIDEBY ANDREW CHRISTY AND SYDNEY BLOOMENTHAL
RYERSON PHYSICAL LABORATORY, UNIVERSITY OF CHICAGO AND RADIO
CORPORATION OF AMERICA, NEW YORK CITY

(Received November 19, 1929)

ABSTRACT

The bands of the *A* and *D* systems of PbO are composed of single *R* and *P* branches only. The combination principle has been applied to the lines of these branches and the rotational constants of the molecule have been determined. The bands of PbO have been assigned previously to three systems, *A*, *B*, and *D*, all three having the final state in common. The nuclear separation of this final state is found to be 1.9207×10^{-8} cm, that of the upper state of *A*, 2.0927×10^{-8} cm, and of the upper state of *D*, 2.0424×10^{-8} cm. No *Q* branches have been found in either of the two systems, indicating that all the electron states involved have the same value of Δ . It is shown that the electronic levels of the two systems investigated are singlets. All the electron states involved are, in all probability, $^1\Sigma$ states.

THE purpose of this work is to determine the rotational constants of the lead oxide molecule and if possible its electron states. The vibrational analysis and the isotope effect are treated in the preceding paper, in which it is also shown that practically all the bands in the spectrum of PbO may be assigned to three systems, *A*, *B*, *D*, all having the final electron states in common.

The following bands were used for the fine structure analysis:

0, 2 $\lambda 5459.4$ <i>A</i> system	0, 5 $\lambda 6160.5$ <i>A</i> system
0, 3 $\lambda 5677.8$ <i>A</i> system	0, 2 $\lambda 3485.7$ <i>D</i> system

The spectrograms¹ from which the lines were measured were taken with a sample of uranium lead of atomic weight 206.1. The stronger lines, therefore, are due to Pb²⁰⁶O. In addition to these, however, there are, near the head of each band, especially in those of *A*(0,2), *A*(0,3), and *A*(0,5), fainter lines due to Pb²⁰⁸O. It cannot be determined with any certainty whether or not lines due to Pb²⁰⁷O are present. If the lines of Pb²⁰⁸O are due to the fact that the uranium lead has been contaminated with ordinary lead, we should expect the lines of Pb²⁰⁷O to appear with intensity approximately half as great as those of Pb²⁰⁸O.² Since most rocks contain traces of ordinary lead, it may be that in the process of extraction uranium lead has been contaminated with ordinary lead. Furthermore the atomic weight of pure uranium lead was found to be 206.06³ while the atomic weight of the sample

¹ For a detailed account of the experimental work, see preceding paper.

² Aston, *Nature* 120, 224 (1927). Ordinary lead consists of isotopes 208, 207, 206, in the ratio of 7, 3, 4.

³ G. Kirsch, "Geologie und Radioaktivitat" p. 138.

from which these spectrograms were made was 206.1, indicating that the sample used must have contained traces of ordinary lead.

The lines of the $\lambda 5677.8$ Å and $\lambda 6160.5$ Å bands were measured from first order plates, those of the other two from second order plates. The measurements of individual lines are considered to be accurate to within 0.1 cm^{-1} .

The bands of the two systems which were examined consist of single R and P branches, indicating that we have to do with a transition between two singlet electron levels having the same $\Lambda(^1\Sigma - ^1\Sigma$ or perhaps $^1\Pi \rightarrow ^1\Pi)$. In the more favorable cases, for large rotational quantum numbers, lines from the R and P branches fall in such a way as to form close doublets, the doublets becoming single lines as they approach the head. All the bands of PbO so far investigated degrade to the red.

Assuming rotational terms of the form

$$\text{const} + BJ(J+1) - DJ^2(J+1)^2 + \dots$$

where⁴ $B = B_v = B_0 - \alpha v = B_e - \alpha(v + 1/2)$, we may define the usual combination differences $\Delta_2 F'(J)$ and $\Delta_2 F''(J)$ as

$$R(J) - P(J) = \Delta_2 F'(J)$$

and

$$R(J-1) - P(J+1) = \Delta_2 F''(J)$$

$\Delta_2 F(J)$ being

$$\Delta_2 F(J) = 2(B - 2D) + 4(B - 3D)J - 12DJ^2 - 8DJ^3 + \dots$$

$\Delta_2 F'(J)$ should be the same for the (0,2), (0,3), and (0,5) bands of the A system, and $\Delta_2 F''(J)$ should be the same for the (0,2) band of the A system and for the (0,2) of D , since both these systems have the final level in common. These combinations have been found and tested for over thirty members, at least, of the R and P branches in each of the above bands. Samples of values for $\Delta_2 F^{(0)'}(J)$ of the A system for the three bands mentioned above are given in Table I, while the corresponding values of $\Delta_2 F^{(2)''}(J)$ of (A) and (D) are given in Table II.^{4a} The values of $\Delta_2 F^{(3)''}(J)$ (A), $\Delta_2 F^{(5)''}(J)$ (A) and $\Delta_2 F^{(0)'}(J)$ (D), for small, medium, and large values of J , are given in Table III, columns 2, 3, and 4. The correct value of J is given in column 1 of the latter three tables. The occasional large discrepancies between the corresponding $\Delta_2 F$ values in Tables I and II are due partly to over-lapping of the two branches R and P , especially in the regions near the head, and partly to the superposition of lead and copper lines or their ghosts on the lines of the bands. It is thought inadvisable at present to give more complete tables of $\Delta_2 F$ values or tables of the wave-numbers of the lines which have been measured in all these bands. These tables will be given later, when a more thorough investigation of these three systems of the PbO molecule has been made.

⁴ The symbol v is used in this work for the vibrational quantum number.

^{4a} In $\Delta_2 F^{(0)'}$, $\Delta_2 F^{(2)''}$, etc., the subscript of F indicates the value of the vibrational number v .

The constants of the molecule were obtained by the graphical method outlined on pp. 172-173 of the Report.⁵ The values of $\Delta_2 F/J$ were plotted

* These systems have the final state in common.

It is estimated that the values of B are accurate to within 0.1 percent, hence the calculated values of r_0 (nuclear separation) should be accurate to within 0.05 percent. In this analysis the value of B_0'' was not obtained directly but was extrapolated from the known values of B_2'' , B_3'' , and B_5'' . Since B_2'' was obtained from two bands, i.e. 0,2 of (A) and 0,2 of (D), twice as much weight was given to this value as to the two others.

R. T. Birge⁶ has found the following empirical equation from a study of a large number of bands: $2B_0\alpha/\alpha=1.4\pm 2$. Substituting the corresponding values for the lower electronic level of the A system we find: $2\times 3.73\times 30616/722.3\times 0.0183=1.7$. Using this value for the above fraction, α for the upper electronic levels for the systems A and D was calculated. In calculating r_0 , the atomic weight of uranium lead was taken to be 206.06.⁴ In all the calculations the values of the auxiliary constants used are those given by Birge.⁷

It has been remarked above that in all the bands investigated no Q branches were observed.⁸ The absence of a strong Q branch indicates that $\Delta\Lambda=0$.⁹ The only possibilities, therefore, are that we are dealing with such transitions as $^1\Sigma\rightarrow^1\Sigma$, $^1\Pi\rightarrow^1\Pi$, $^1\Delta\rightarrow^1\Delta$, etc. It has been stated that the bands of the A and D systems consist of single R and P branches. Thus it is not possible that either the upper or lower levels of the system or both are narrow multiplets, for, in that case, we would expect additional branches to appear. It is evident, therefore, that the levels in question are singlets. (The bands of the B system have also been examined with this fact in mind. As far as can be ascertained from a cursory investigation of enlargements

⁶ R. T. Birge, Phys. Rev. 31, 919 (1926).

⁷ R. T. Birge, Phys. Rev. Supplement 1, 1 (1929).

⁸ R. Mecke, Die Naturwissenschaften 17, 133, stated that the three systems A, B, and C are probably due to a $^3\Pi\rightarrow^3\Sigma$ transition, the upper electron states of A, B, and C being the components of the $^3\Pi$ state. It has been shown in the preceding paper that practically all the bands assigned by Mecke to system C are actually members of system B. This work shows that system A is not due to a $^3\Pi\rightarrow^3\Sigma$ or even to a $^1\Pi\rightarrow^1\Sigma$ transition.

of these bands, their appearance is similar to those of the other systems. If there is a Q branch in these B bands, it must be very weak.)

R. S. Mulliken⁹ has given the theoretical intensities to be expected in transition between two singlet electronic levels, both of which have the same value of Λ . The equations are:

$$i_Q = a(2J+1)\Lambda^2/J(J+1)$$

$$i_P = a(J^2 - \Lambda^2)/J$$

$$i_R = [a(J+1)^2 - \Lambda^2]/J+1$$

In these equations the Boltzmann factor has been omitted, since for low values of J and B and high temperatures this factor is essentially equal to 1. It may be shown readily from the above equations that if $\Lambda = 1, {}^1\Pi \rightarrow {}^1\Pi$, there is a weak Q branch; the intensity of the first Q line is three times as great as that of the first R line, the intensities of the other Q lines, however, decrease rapidly for higher values of J . For $\Lambda = 2, {}^1\Delta \rightarrow {}^1\Delta$, we have qualitatively the same result but the first Q line is very much stronger, and the intensities of the other lines decrease less rapidly.

It is obvious from an examination of the plates and enlargements of these bands that we do not have a ${}^1\Delta \rightarrow {}^1\Delta$ transition, for in that case a Q head should be strong enough to show and there is no evidence of such head in our plates. The only alternative, therefore, is that the bands are due either to ${}^1\Pi \rightarrow {}^1\Pi$ or ${}^1\Sigma \rightarrow {}^1\Sigma$ transitions. In our opinion the latter is the more reasonable as it seems improbable that all the electron states of this molecule should be ${}^1\Pi$ states with no ${}^1\Sigma$ state present. For a final decision, however a more accurate study of the bands must be made, with plates of greater dispersion.

It has been shown in the preceding paper that the three known systems of the PbO molecule, A , B , and D , have the final state in common, hence we may reasonably assume that this state is the normal state of the molecule. The nuclear separation $r_0 = 1.9207 \times 10^{-8}$ cm., while larger than that of other oxides¹⁰ so far investigated, is comparatively small for such a heavy molecule. This seems to indicate that the normal state is fairly stable.

If we assume that in the formation of PbO only the four electrons of Pb in the P shell are greatly influenced by the O atom, then the configuration of outer electrons in the PbO molecule should resemble that of CO with a ${}^1\Sigma$ state as the normal state of the molecule. It appears to us that the data on hand are neither sufficiently accurate nor extensive to warrant any further conclusions as to the electron states of PbO. The fine structure analysis of the bands is being continued in Ryerson laboratory, in order to determine this and other related points.

In conclusion the writers wish to acknowledge their indebtedness to Professor R. S. Mulliken, who proposed this problem, for his advice and many helpful suggestions.

A LABORATORY METHOD OF PRODUCING
HIGH POTENTIALS

BY G. BREIT, M. A. TUVE, and O. DAHL

DEPARTMENT OF TERRESTRIAL MAGNETISM, CARNEGIE INSTITUTION OF WASHINGTON

(Received November 19, 1929)

ABSTRACT

Details are given of the experimental arrangement by which, using Tesla coils in oil, very high potentials have been produced and measured. Excited at the rate of 120 sparks per second Tesla coils have been operated at 3,000,000 volts in ordinary transformer oil at atmospheric pressure. In oil under a pressure of 500 pounds per square inch, voltages as high as 5,200,000 have been produced with intermittent excitation. These voltages (peak values) are measured by a simple capacity-potentiometer, in which an insulated electrode "picks up" a known fraction of the total voltage, this fractional voltage being measured by means of a sphere gap. Measurements are given of the voltage-distribution along Tesla coils. Calculations and measurements of the efficiency and power-output of such coils show that at 120 sparks per second, a coil operating at 5,000,000 volts provides sufficient power, if used to accelerate helium nuclei in a suitable vacuum-tube, to yield the equivalent of about 2,600 grams of radium.

THE importance of obtaining sources of high-speed electrons and atomic nuclei for physical investigations is so obvious that an explanation of the aim of the present work is hardly needed. It may be permitted however to say a few words about the part played by experiments with penetrating radiations in the past and to mention briefly some of the current problems for the solution of which the development of new and more powerful sources than have been available appears to be essential.

The Rutherford-Bohr atomic model was suggested by experiments on the scattering of α -particles. Their penetrating nature made it possible to obtain a simple interpretation of the results. The understanding of the nature of the solid state has received its main stimulus from experiments following Laue's discovery. Here the penetrating x-ray quanta offer direct and clear information; similarly with the Compton effect and with Rutherford's nuclear disintegration experiments. These very important experimental facts forming the foundation of modern theoretical conceptions have come out of experiments employing high-energy quanta, electrons, and α -particles. The historical reason for the importance of high-energy experiments is, of course, that classical physics corresponds to energy-jumps of zero-value so that the larger the energy concerned the more radical the departure from classical physics and the more interesting the phenomenon. Quantum mechanics has explained in recent years all of the fundamental facts in ordinary atomic structure. According to current theoretical opinion it is highly improbable that one shall find a serious contradiction to the present theoretical scheme by studies of line and band spectra. Apparently

the main unsolved questions at present are Dirac's $\pm m$ difficulty and the combined relativistic treatment of matter and electrodynamics. The first of these as shown by Klein becomes particularly pronounced for potential walls of high absolute value. It may be hoped that light may be thrown on the question by studies on nuclei by means of particles with high kinetic energy.

The precise form of the equation for one electron is intimately concerned with the $\pm m$ difficulty. It will be noted that by studying the intensity of scattering of recoil-electrons by hard γ -rays, Skobeltzin¹ has recently obtained evidence for preferring Dirac's equation for a free electron to the older Schroedinger form. His intensities agree with the calculations of Klein-Nishina, which use Dirac's equation, rather than with the older calculations of Dirac employing the Schroedinger equation without spin. It is not altogether clear at present to what extent Skobeltzin's experiments prove the validity of Dirac's equation or deal only with the presence of the electronic spin. It is clear however that when repeated with still more penetrating radiation they will give very important evidence. The practical approach to the combined treatment of matter and the electromagnetic field is also in all probability to be obtained by studying systems containing two particles in a state of rapid relative motion. Experiments on atomic nuclei giving their energy-levels, conditions for disintegration, etc., may be expected to offer new and valuable evidence for these still unsolved theoretical points and may besides suggest quite different questions and difficulties which do not come up in dealing with phenomena outside atomic nuclei.

We have thought it worth while therefore to construct high-potential equipment of convenient laboratory dimensions to make it possible to perform experiments on high-velocity particles. The electrical problem of producing high potentials was solved without much difficulty over two years ago.² The construction of high-potential vacuum (x-ray) tubes has proved more difficult but is at present sufficiently advanced to make a progress-report of interest and to show that the Tesla coils used for producing high potentials are suited for supplying the potentials to vacuum-tubes. The details of the electrical arrangement not having been published before we have divided the matter into two parts the present paper being concerned with the electrical arrangements and the one following with the construction and experiences with high-potential vacuum-tubes.

The apparatus used for producing high potentials is old and well-known under the name of Elihu Thomson or Tesla coils. Since their invention Tesla coils have been known to give possibilities of producing with limited means potentials of the order of one million volts.³ They have commonly been used in air, the insulating qualities of which constituted a limitation on their performance. It is difficult to construct Tesla coils of sufficiently large dimensions to prevent corona and sparking in air. The energy con-

¹ D. Skobeltzin, *Nature* **123**, 411 (1929).

³ M. Wolfke, *Phys. Zeits.* **24**, 249 (1923).

sumed in the corona and sparking is so large that the Tesla coil ceases to operate as a resonance-transformer on account of the high damping and loses most of its advantages. If the dimensions of the coil are sufficiently large to prevent corona its electrostatic capacity becomes inconveniently large and necessitates unnecessarily cumbersome primary circuits. The main point in the operation of Tesla coils is therefore to prevent corona and sparking by using the high-potential parts of the coil in a medium of high dielectric strength. For a number of years two of us had in mind the possibility of using Tesla coils in a vacuum or in some other insulating medium. The method described here employs transformer oil which we have found sufficient for roughly five million volts when used under pressure and three million volts at atmospheric pressure. These figures are somewhat arbitrary, simply being the voltages obtained in the laboratory and not representing final limits in the voltages obtainable with oil. No doubt still higher voltages can be obtained by using oil for insulation. The practical advantages of oil over vacuum for preliminary trials are obvious when the question of repairs, changes in design, and baking out of metal parts is considered. The ultimate possibility of using Tesla coils in a vacuum is of course not excluded.

EXPERIMENTAL ARRANGEMENTS

The principles underlying the operation of a Tesla coil are well known and need not be explained here in detail. The important thing is that two resonant oscillatory electrical circuits, the primary and the secondary, are coupled magnetically to each other. The primary circuit has a large capacity and a small inductance while the secondary (the Tesla coil) has a large inductance and a small capacity. The condenser of the primary circuit is charged to a high potential (of the order of 30 or 60 kv) and is allowed to discharge suddenly through a spark-gap and the primary inductance. An oscillatory discharge takes place. The secondary circuit being in resonance with the primary the energy is transferred with fair efficiency to the secondary before the damping appreciably reduces the amplitudes of oscillation. In the set-ups used the peak-voltage of the secondary circuit corresponds roughly to the transfer of one-fourth of the energy of the primary condenser to the secondary. The resonant frequencies of the coils used have been of the order of 100,000 cycles per second.

Figure 1 shows the arrangement for a Tesla coil in oil under pressure, with which over 5,000,000 volts were obtained. The condenser is fed on rectified current supplied by an x-ray machine. The primary gap is of the stationary type.* The use of rectified current is advisable if power consumption and large charging currents of the primary condenser are to be avoided. The arrangement can also be used without a rectifier, the primary condenser being then fed by a transformer and discharged through a syn-

* It can be made cheaply out of ten-inch hollow zinc-balls used for decoration purposes and usually furnished in the form of two hemispheres. For long and continued use heavier electrodes are preferable.

chronous gap. For our highest voltages we have been forced to use the rectifier because our power-lines have the unusually small capacity of 50 KVA.

The synchronous gap has been used up to 3,000,000 volts secondary output. The transformer was fed on 60-cycle alternating current and the condenser was discharged 120 times per second. No pressure had to be applied to the oil for this voltage. Even at low voltages, however, we find it convenient to use the rectifier when possible because by so doing a weak spot in the insulation of the secondary can be detected before electrical breakdown causes too much damage. In our experiments with oil at atmospheric pressure, corona at the ends of the Tesla coil limited the voltage obtainable to about 3,000,000. With the high-pressure arrangement corona has not given any serious difficulty. Insulation between turns limited the voltage in this case to about 5,000,000 volts.

Fig. 1. Schematic diagram Tesla coil in oil under pressure.

Power-supply for the primary condenser.—For the production of 3,000,000 volts we used a small transformer giving about 30,000 volts and operating on 60 cycles with approximately a 3-kilowatt rating, kindly loaned to us by the Washington Navy Yard. For the intermittent production of the higher voltages we used a 10-KVA Kelley-Koett x-ray machine operating on a 220-volt 60-cycle supply. This or any other reliable x-ray machine contains the transformer mechanical rectifier and controls needed for charging the condenser. A potential of 120,000 volts could be supplied by the machine. In our experience we have rarely used it above 70,000 volts.

Condenser.—The work was begun by using a set of glass-in-oil Telefunken condensers loaned by the Washington Navy Yard; these had previously been used in a high power Navy spark-transmitter. Sixteen of these sufficed for the production of 3,000,000 volts. The capacity of each was 0.038 microfarad and each unit stood 15,000 volts (peak). For higher voltages however

we constructed a special condenser similar to that used by Anderson for exploding wires. Lead foil 0.003 inch thick was applied to each side of 200 glass plates. The plates are 40 inches square of somewhat irregular thickness approximating one-eighth inch, being ordinary B-grade double-strength window-glass. They are assembled in wooden racks in air and constitute a generally useful as well as comparatively inexpensive piece of laboratory equipment. Figure 2 shows a condenser including part of the lower and most

Fig. 2. View of section of the glass-plate condenser ($C = 1.6\mu f$, 30,000 volts).

of the upper rack. The plates are spaced one-half inch apart. For reasons which are somewhat obscure it is essential that the plates be spaced to prevent breakage when the condenser is discharged. We found it very convenient to fasten the lead foil to the plates simply by an oil-film. Any lubricating oil of a not too heavy consistency is satisfactory, but linseed oil seems to be the most convenient material for this purpose both on account of being easily squeezed into a thin film under the lead foil and because it dries around

the edges. A margin of about 4 inches is left on the glass around the foil, allowing the plates to go up to a sufficiently high potential and yet providing a safety-gap around the edge of the glass plate. In two years we have not had a single puncture of the plates although the condenser has been repeatedly at the flash-over point. In case of breakage however the plates can be taken out of the racks with relative ease. Pieces of rubber tubing inserted between plates close to the edges help to secure a uniform distance between them. The side of the racks shown in the figure is provided with two pieces of angle brass (only one is visible) which serve as supports for the connectors to the plates and as bus-bars. The opposite side (not shown in the figure) has each bus-bar split into two insulated sections thus allowing the use of the plates either all in parallel, in two sections in series, or in four sections in series. The capacity of all plates in parallel is about 1.6 microfarads. The maximum voltage which can be used with the plates in parallel varies between 30,000 and 40,000 volts depending on the type of external circuit. As a rule a high inductance in the external circuit allows one to use a

Fig. 3. Tesla coil and primary, showing the spun-zinc balls which serve as corona-shields at the ends of the Tesla coil.

higher voltage on the condenser. If the voltage exceeds this limit a local flash-over occurs around the edge of a plate when the primary gap discharges. The exact nature of the flash-over is hard to explain but it is undoubtedly due to transients. When it occurs the primary circuit becomes inefficient but in our experience no particular damage to the condenser takes place. With the four sections in series we have used this condenser without flash-over at 120,000 volts.

Primary of Tesla transformer.—This as shown in Figure 3 is made of several turns of spirally-wound copper tubing. Some of the most efficient circuits employ only two turns.

Tesla coil.—This is shown also in Figure 3. It is convenient to wind a high-voltage Tesla coil on a piece of Pyrex glass tubing as supplied by the Corning Glass Works with an approximate diameter of 8 cm and length of about one meter. The wire is generally wound without spacing and always in a single layer. The ends are protected by approximately spherical caps, those shown in the figure being 25 cm in diameter. When the Tesla coil is

immersed in oil it is important to eliminate the air which is likely to be trapped between the wires and the glass. If silk-covered wire is used soaking in oil is often sufficient to draw it in by capillary action. Vacuum impregnation is often advisable. For this purpose the coil is put in a tin tray and inserted into a horizontal piece of 6-inch pipe. The pipe is closed, exhausted, and oil is let in slowly with the vacuum-pump running. When the tray is full the pump is disconnected, the tray is taken out, and the coil is ready for use. Our best coils were made of No. 38 or No. 40 B.S. gauge copper wire, 5,000 to 7,000 turns. Either double silk, silk enamel, or the especially heavily enameled No. 40 wire (made by the General Electric Company) are satisfactory. It often happens that there are flaws in the insulation of the wire. These cause sparks between turns as soon as the coil is used and the coil is often burned out at such points. Having thus found out the weak points a few turns are unwound, the wire is scraped carefully at the ends, and is spliced; such a repaired coil is usually better than a fresh one. Insulation between turns usually gives no trouble up to 3,000,000 volts peak.

A screw is fixed permanently in the ball so that the ball can be screwed as a whole into a tapped hole in a brass end-piece fixed on the axis of the Tesla at its end. Incidentally, Houston's water putty made by the Gold Medal Polish Company (Racine, Wisconsin) provides a very convenient means for fastening attachments to Pyrex tubing. In most of our experiments the Tesla coil has been supported in the oil by a loop of silk fish-line at each end, which stands the full voltage to ground without trouble.

Oil and high-pressure tank.—Light transformer oil (not switch oil) purified by passing through a centrifuge has been used. Most of the oil employed by us has the trade name Transil 10 C. At its best clean oil is broken by about 46,000 volts across a 1-mm gap; in thicker layers its apparent dielectric strength is always less than this. The effective dielectric strength also depends to a large extent on the state of the electrodes between which the discharge takes place. No exact quantitative values can be assigned to it in our experience except by allowing a considerable safety-factor. It has proved possible to improve the performance of the oil by continued and judicious use. A preliminary discharge is often likely to take place while using a Tesla coil before the dielectric strength of pure oil is reached. We find it advantageous to "break in" the oil by allowing such discharges to occur. The procedure in this "breaking in" process is to bring up the Tesla voltage gradually. For very low voltages the caps on the ends of the coil show no discharge. As the voltage is brought up occasionally a corona "tree" shoots out from one of the caps into the oil. If the voltage is held at such a value that the "tree" occurs only seldom, the "trees" disappear after continued use. The voltage may then be brought up higher, "trees" occurring again occasionally and again disappearing after continued running. This process cannot be continued indefinitely but it is quite essential in improving the performance and obtaining as high a potential as possible. If the "trees" refuse to disappear it is often advisable to lower the potential to a point where they occur less frequently and to make them disappear

there. The "breaking in" of the oil and cap surface can be done either with a Tesla using 60-cycle excitation with a synchronous primary gap, or else by the intermittent primary sparks produced when using the x-ray machine. We have no special evidence of the superiority of either method. The synchronous gap is likely to shorten the time required but it is also likely to carbonize the oil if too heavy discharges occur. Its main danger lies in burning out the fine wire of the Tesla at points where the insulation on the wire is defective. We have obtained 3,000,000 volts with a Tesla used on 60-cycle synchronous gap excitation, the ends of the Tesla being protected by 5-inch spun copper caps. The mode of oscillation of the coil was such that the middle of it was at ground while the ends were at each instant at equal and opposite potentials. Each 5-inch cap was therefore at 1,500,000 volts corresponding to a gradient of 240,000 volts per cm. We did not find it practical to use much higher gradients in oil at atmospheric pressure, the performance of the apparatus becoming unreliable due to the corona from the caps. Also the apparent gradient to which the oil may be brought up depends on the caps used. An increase in the diameter of the caps makes it possible to bring them up to a somewhat higher potential. However the gain in potential is always less than would be calculated from the diameter. The exact reason for this we do not know but the obvious difficulty of having a perfectly shaped light metal sphere of large diameter, and of keeping it clean and polished, has probably much to do with it. The nature of the "breaking in" process we also do not know much about. It may be connected with removing dirt or microscopic particles of moisture from the electrodes or even with a local purification of the oil due to driving moisture or small air bubbles away from regions in which the electric field is large. Our main concern with regard to the production of high voltages has been the purely practical one of using oil at as high a value of the electric field as possible in order to test the voltage and power-output limitations of the method.

To improve the performance of the oil beyond that which was obtainable by ordinary purification and "breaking in" at atmospheric pressure we resorted to the pressure-method.⁴ The pressure container is shown to scale in proportion to the Tesla coil in Figure 1. It is a hammer-welded iron tank originally made by the M. W. Kellogg Company of Jersey City for use as a steam separator. It is designed for a working pressure of 450 pounds per square inch in accordance with the standard boiler safety-code. [The importance of precautions in the use of high pressures in large containers cannot be over-emphasized.]

The tank was furnished with solid manhole plates which were later machined with proper openings for the insulating bushings and peep-holes (not shown in the figure). A peep-hole was put in each manhole plate. Each hole, three inches in diameter is covered with two-inch plate-glass. The inside of the tank was illuminated with two automobile headlights, current being supplied through an ordinary spark-plug screwed into a third manhole of the crab type in one head of the tank. This third manhole has been

⁴ F. Koch, *Elektr. Zeits.* **36**, 85 and 99 (1915).

omitted in the figure. The pressure was applied to the oil by means of a carbon dioxide cylinder shown in the figure as "air-pressure cylinder." On account of the increase of volume of the tank under internal pressure and on account of the compressibility of the oil it is necessary to supply extra oil (several gallons) when pressure is applied. This is done by connecting the carbon dioxide pressure-cylinder to the auxiliary oil tank shown in the figure.

The "breaking in" of the oil is essential also in this high-pressure arrangement. It is difficult to give exact figures for the improvement in the dielectric strength due to pressure. Roughly a factor of two is correct in our experience. The limitation which we encountered in the use of Tesla coils in oil under pressure was due to insulation between turns and not to "trees" (corona) off the caps. With longer Tesla coils it would be doubtless possible to exceed our voltages. The maximum which we obtained was 5,200,000 volts. The coil was wound with ordinary No. 40 enameled and silk-covered wire. The caps were 20 cm in diameter and the length of winding was approximately 90 cm. The mode of oscillation was again the half wave-length, that is, middle at ground and ends at opposite potentials. The application of pressure improves the insulation between turns as well as the insulation around the caps, there apparently always being a film of oil between turns. The improvement for the caps, however, proved to be so large that they offered no serious difficulty. The oil is purified at intervals by means of a Hydroil centrifugal purifier.

Measurement of high potentials.—We have used two methods of estimating the potentials. The first was used purely qualitatively although it can be developed into a quantitative one. It consisted in observing the deflection of a cathode-ray beam in a low voltage cathode-ray oscillograph. The latter was of the Johnson type made by the Western Electric Company giving cathode rays of 300-volt velocity observed visually on a fluorescent screen. The cathode-ray tube was put vertically in a wooden box the outside surface of which served as a support for a set of vertical grounded wires. These allowed only horizontal fields to affect the cathode rays. The sensitivity of the tube to electric fields inside the shield was determined experimentally by putting it in known fields produced by an electron-tube oscillator. One centimeter deflection on the screen could after the calibration be interpreted as a known electric field. When the cathode-ray box was put in the neighborhood of the Tesla coil the deflection on the screen was observed and the oscillating electric field due to the coil thus determined.⁵ From a knowledge of the potential distribution on the coil and the distances involved the numerical value of the potential can be computed. The difficulty of this method lies in the extreme weakness of the trace on the fluorescent screen

⁵ For this experiment the Tesla coil was supported in an open wooden tank containing the oil, although for experiments at atmospheric pressure we now use a 1500-gallon steel gasoline storage tank with about one-fourth of the cylindrical surface cut away. No particular loss of efficiency is occasioned by operating these high-frequency coils inside of a metal tank. This is clear, of course, from the results with the thick-walled high-pressure tank.

due to the extremely short duration of the high potential on the Tesla coil. The visibility of the trace being so low no quantitative measurements could be made. The estimates thus formed were checked however by measurements by the second method. Photographic registration of the cathode ray, as in the Dufour cathode-ray oscillograph, would make the first method quantitative and we mention it mainly for this reason.

The second method can be described as a capacity-potentiometer or "pick-up" measurement. The principle is shown in Figure 1. The manhole on the right of the high-pressure tank is provided with an insulating bushing which supports a voltage "pick-up" ball. Since the potential on the Tesla coil alternates with a high frequency (approximately 100,000 per second) the potential assumed by the pick-up ball is determined by the capacities between the Tesla coil and the ball as well as between the ball and the ground. In order to know the potential of the coil it is sufficient therefore to measure the potential on the "pick-up" system and to determine the ratio of the potential on the coil to the potential on the "pick-up." The measurement of the potential on the "pick-up" system is made by means of a sphere-gap and the ratio of the two potentials is determined at low voltages where the potential of the Tesla coil can be measured directly. The direct measurements of the Tesla-coil voltages in the low range have been made in two ways. The most direct method is to connect a sphere-gap across the coil. In doing this care is taken to have the high-potential lead to the sphere-gap removed as far as possible from the "pick-up" ball so as not to change the relative distribution of capacities. Since this can never be done perfectly, although in general it leads to underestimating the true voltage, we have also determined the potential ratio, or calibration-factor, by a somewhat different method free from this objection.

The second way of determining the calibration-factor makes use of the fact that the potential at the middle of the Tesla coil is the same as that of the ground, and that a small capacity around a small section of the coil at its middle does not change appreciably the voltage-distribution along the coil. Thus the coil is provided with taps exactly at the middle as well as at one and two centimeters to each side of the middle. The coil is excited by sustained oscillations from an electron-tube oscillator. A bifilar electrometer is connected across the middle tap and one of the others, and another bifilar electrometer is connected across the measuring gap. The ratio of the two measured potentials gives therefore the ratio of the potential across one centimeter of the Tesla coil at its middle to the "pick-up" potential. In order to determine the calibration-factor it is now only necessary to find the ratio of the potential across the whole Tesla coil to the potential across a centimeter of it at its middle. This was determined by finding the potential distribution along the coil by special experiments.

It may be shown by calculation that the change in the resonant frequency of a Tesla coil when a capacity is connected across a section of it is proportional to this capacity and the square of the voltage across the section in question. This calculation presupposes that the change of frequency dealt

with is small. Model Tesla coils were built with taps and the "detuning" effects were observed when a small fixed condenser was connected across the various sections. The square roots of the detuning effects $(\Delta C)^{1/2}$, when ΔC is the capacity-change required to retune an oscillator coupled to the Tesla coil, gave the potentials across the separate sections and hence by addition the potential distribution along the coil. The magnitude of the fixed capacity used was varied so as to make sure that it was small enough and not sufficient to cause partial resonance of a part of the coil which would vitiate the measurements. The condenser employed to produce the capacity-changes was made of two circular plates about 5 cm in diameter separated by a thin sheet of mica and thus had a fairly small capacity to ground. This capacity was sufficient to require a correction because it was found that if the condenser was connected to one of the taps it had a measurable detuning effect on the Tesla coil. This detuning effect was therefore ascertained for all the

Fig. 4. Voltage-distribution curves for Tesla coils (points are plotted for corrected data only; the uncorrected points are almost indistinguishable from these on the scale of the figure).

taps and corrected for by subtracting it from the detuning effect of connecting the condenser across two adjacent taps. The remaining number gave the detuning due to a capacity across the two taps without having a capacity to ground. This correction reduced the resulting form-factor only two or three percent, however, (see Figure 4). When different condensers were used the voltage-distribution curves corrected for the capacity to ground of the "probing condenser" checked closely for different capacities of the condenser used. Such measurements were made on Tesla coils wound with different sizes of wire and with different caps on the ends. The voltage-distribution curves proved to be independent of the size of wire used for winding the Tesla coil. Experiment shows however that it depends appreciably on the capacity load at the ends and that it is different for different sizes of caps used. The results can be expressed most conveniently in terms of the ratio of the average slope of the voltage-length curve to the maximum slope at the middle of the coil. For coils of the dimensions used by us this ratio or "form-factor"

is 0.77 for coils without caps (Figure 4C), 0.82 for 5-inch cast bronze caps, 0.87 for 10-inch caps. The voltage-distribution thus becomes more linear as the capacity-load at the ends is increased, as would be expected. Knowing the "form-factor" of the coil we obtain the potential across the coil from the potential across one centimeter of it at the middle by multiplying the latter potential by the length of the coil in centimeters and by the "form-factor."

We have ascertained the effects of the capacity of the electrometers used in the measurements by connecting a third electrometer either at the measuring sphere-gap or at the tap across the middle of the Tesla coil. These effects are small and corrected for. The calibrating-factors obtained by the first or second method of measuring the Tesla-coil voltage agree very closely. In both cases we also have made sure that the "pick-up" voltage is due to the potential on the Tesla coil itself rather than to induction from the primary and calibrating circuits by partially or completely detuning the primary circuits from the Tesla coil. This reduces the "pick-up" voltage to zero.

Every calibrating-factor depends on the setting of the measuring gap because the capacity of the "pick-up" system to ground is affected by the distance between the two measuring spheres. A curve for the calibrating-factor against the "pick-up" gap setting is plotted and used in the calculation of the voltage. The corrections due to this cause are of the order of 5 to 10 percent in our set-ups. The measurement of the "pick-up" voltage in actual operation consists in determining the separation between the spheres at which sparks definitely pass between them. The potential across the gap is then obtained from the data of Peek.⁶ The potentials of the secondary gap are generally of the order of from 30,000 to 100,000 volts thus allowing one to make fairly accurate gap-settings. Since voltage-measurements by a sphere-gap may be subject to corrections due to local conditions such as air ionization, surface condition of gap, etc., as a precaution we have checked one of our gaps on 60 cycles against an electrostatic voltmeter and found the results to be in agreement with Peek's data. For our measuring gaps we always employ 25-cm (10-inch) diameter spheres, which are known from the work of Peek to be reliable indicators in the range of voltages used. A sphere-gap does not give as consistent readings immediately after polishing as it does after a number of sparks have passed. Freshly polished spheres will spark occasionally at a greater separation than will "used" spheres for a given voltage. We have always taken measurements with gaps in the "used" condition, leading to lower rather than higher voltage-estimates.

It may be observed that if the oil should become partially conducting under the influence of high electric fields the "pick-up" method would be seriously vitiated and would tend to give exaggerated values to the Tesla voltage. We have taken care therefore to make sure that this is not the case.

⁶ F. W. Peek, Jr. Dielectric phenomena in high-voltage engineering (McGraw-Hill, 1920) Chapter IV; Trans. A. I. E. E. **34**, 1857 (1915); J. Franklin Inst. **197**, 1 (1924) and **199**, 141 (1925); Smithsonian Inst. Report for 1925, 169 (1926). Also L. W. Chubb and C. Fortescue, Proc. A. I. E. E. **32**, 627 (1913).

Our main evidence lies in the fact that the measured Tesla voltages, with a given primary setting, are independent of the position of the "pick-up" (each position of course being separately calibrated at low voltage) as long as there are no "trees" from the caps in the oil. Since at low voltages used in the electrometer-calibrations there is absolutely no possibility of a non-uniform oil-conductivity we conclude that the oil-conductivity is uniform also when high potentials are used unless a visible breakdown occurs as shown by "trees" or bolts in the oil. In the second place we find that the measured Tesla-coil voltage is proportional to the potential to which the primary condenser is charged which is determined by the setting of the primary gap. This again would not be the case if the conductivity of oil and invisible discharges played any part in the measurements. If insufficient care is exercised in preventing corona in air or the discharges along the surface of the oil from the high-potential connections of the measuring gap, too low values of the Tesla voltage may result. The only deviations from linearity which we have observed have been due to these causes.

Data on the efficiency of Tesla coils.—We have made rough measurements of the potentials developed by Tesla coils with various sizes of caps in terms of the potential of the primary gap. The measurements given in the table were all made with a primary voltage of 6500 and with half wave-length excitation of the Tesla coil. V_T represents the total voltage between caps, measured by the capacity-potentiometer method. Each cap is therefore charged to a voltage $V_T/2$ above ground. The primary circuits and the coils may be rated either from the point of view of having a certain maximum usable primary potential or else on the basis of having a certain maximum number of plates for the primary condenser. For this reason we tabulate both the ratio V_T/V_P giving the voltage gain-factor of the Tesla over the primary and applying therefore to the case when the primary potential is the limitation, and also $C_P V_P^2/V_T^2$ expressed in micro-microfarads. The latter figure gives the effective capacity of the Tesla coil which for this purpose is defined to be such a capacity C_T which would attain a voltage V_T if all of the energy $C_P V_P^2/2$ of the primary condenser were transferred to the capacity C_T . The point is that a given number of plates available for the primary condenser whether used all in parallel or in several groups in series gives roughly the same maximum value of $C_P V_P^2$ and therefore if the limitation lies in the primary condenser a small value of $C_P V_P^2/V_T^2$ is an advantage.

It is seen from the table that if the primary voltage is fixed a small primary inductance and a large primary condenser constitute the best circuit. If however the number of glass plates available for the condenser is limited it is perhaps at times better to use a reasonably large number of primary turns and therefore less primary capacity but a higher voltage by subdividing the condenser into sections used in series. A too large number of sections in series is of course not practical, leading to overvoltages and increase of circuit-inductance. A too small primary inductance however is also frequently harmful, leading to explosion-like flash-overs of the con-

denser. The use of the table is therefore only to select rough values for the circuit-constants. The best arrangement is found afterwards by trial. The table applies to the particular circuits which were made up of the Telefunken condensers and therefore takes account of the particular lead-inductances used with them.

The table shows the relatively high energy efficiency of the Tesla coil, which is capable of storing in its very small capacity about one-fourth of the energy of the primary circuit. This is made clear by comparison of the

TABLE I. *Data on efficiency of Tesla coils.*

Caps	Primary turns	Primary capacity in microfarads	Transformation ratio V_T/V_P	$C_P V_P^2 V_T^2$ in micro-microfarads

last column of the table with the calculated capacities of the caps (remembering that each cap is charged only to $V_T/2$ above ground). Now a capacity of 1.5 microfarads at 30,000 volts contains 675 joules so that 170 joules can be put into the capacity of the Tesla coil. Even if it should be dissipated in one ten-thousandth second (about 10 cycles at a frequency of 10^5) this gives an instantaneous power of 1.7×10^3 kilowatts. By direct tests we find that a Tesla coil is able to feed about 20 megohms without having its voltage decreased to less than about half. Since insulation, rather than electrical efficiency, is the limiting factor at high voltages, the voltage under load may

be brought up to that obtained without load by supplying extra power in the primary circuit. At 5,000,000 volts the power-consumption through 20 megohms is 1.2×10^8 kilowatts. The instantaneous power available in a Tesla coil is therefore of the order of one thousand kilowatts and at the high potentials produced the coil is capable of delivering fairly efficiently an instantaneous current of 5×10^6 volts/ 2×10^7 ohms = 0.25 ampere. If now the coil is used on 60-cycle current, that is, with 120 primary sparks a second, and if only 10^{-6} second during each discharge (roughly one tenth of a cycle) is counted as effective in feeding a high-potential x-ray tube, the average current is $120 \times 10^{-6} \times 0.25$ ampere = 3×10^{-5} ampere. If only one spark a second is used an average current of 2.5×10^{-7} ampere can be drawn. The synchronous-gap excitation thus gives 1.9×10^{14} five-million-volt electrons per second and the one spark-a-second excitation gives 1.5×10^{12} electrons. For comparison with radioactive sources we recall that the number of α -particles emitted by a gram of radium per second is about 3.5×10^{10} . Thus at 5,000,000 volts one spark a second has sufficient power to drive 0.75×10^{12} α -particles equivalent to 21 grams of radium, and 120 sparks a second would be equivalent to 2600 grams. Such α -particles would have an energy of 10,000,000 electron volts, at least 2,000,000 volts higher than the highest energy α -particles obtainable from radioactive sources. We may conclude therefore that the amount of energy which may be drawn from Tesla coils is sufficient to obtain sufficient numbers of high-velocity particles for disintegration-experiments.

We are greatly indebted to Lieutenant William Klaus formerly of the Washington Navy Yard for arranging the loan of the apparatus with which this work was begun and to the Potomac Electric Power Company for a temporary loan of 400 gallons of transformer oil. Our particular thanks are due to our colleague, J. A. Fleming, for his energetic support and to B. Howard Griswold of Alexander Brown and Sons, Baltimore, Maryland, for temporary financial assistance.

THE APPLICATION OF HIGH POTENTIALS TO
VACUUM-TUBES

BY M. A. TUVE, G. BREIT, AND L. R. HAFSTAD

DEPARTMENT OF TERRESTRIAL MAGNETISM, CARNEGIE INSTITUTION OF WASHINGTON

(Received November 22, 1929)

ABSTRACT

A brief progress-report is made on the results so far obtained in the development of vacuum-tubes to which the very high voltages produced by Tesla coils (greater than 10^6 volts) can be applied. One cascade tube has been constructed which withstood repeatedly a voltage of 1,400,000 volts, and others have been used at lower voltages. This method, originally developed by Coolidge, gives promise of being suitable for voltages of several million, and eventually perhaps even higher. No effort has been made so far to use these tubes with a definite and controlled emission, since experience has shown that single-section tubes operated at several hundred kilovolts have approximately the same voltage-limitation with or without hot cathodes. The chief difficulty with very high-voltage tubes is that of preventing the uncontrollable (cold-cathode) emission which limits the voltage which can be applied. An electrodeless tube which withstood 1,000,000 volts is briefly described.

THIS paper is a brief progress-report giving some of our experiences and the results so far obtained in the development of vacuum-tubes to withstand the high voltages so readily produced by means of Tesla coils. Many different designs of tubes have been constructed, with different kinds of electrodes and variations in vacuum technique, and in general our conclusions parallel those of others working on similar problems using other high-voltage sources. It is very difficult to apply more than 300 to 400 kilovolts to a single two-electrode tube, whatever the design or treatment within practical limits. The reason for this is not known exactly at present. The main difficulties are presumably uncontrollable emission and accumulation of charges on the glass walls resulting in punctures and short-circuiting of the voltage source. We have succeeded, however, in applying Tesla voltages of considerable magnitude to vacuum-tubes by two methods, and these results seem interesting enough to merit a brief description.

(1). *The cascade-tube method*—This is essentially the method developed by Coolidge.¹ We have found it possible to use much smaller tubes for the same voltages by immersing them in oil. Figure 1 shows a picture of a 6-section tube used successfully at 850,000 volts. The overall length is 34 inches; the bulbs are of 100-cc size. A tube of similar design with fifteen 300-cc bulbs and having an overall length of 7 feet has gone up repeatedly to 1,400,000 volts. This tube is shown in Figures 2 and 3. Such tubes are at present always used by us on the pumps. The pump system is an ordinary diffusion or Langmuir pump arrangement. The electrodes are copper tubes

¹ W. D. Coolidge, J. Frank. Inst. 202, 693 (1926).

with rounded ends of as large a radius of curvature as possible, the electrodes being rounded by "spinning" the ends in. We have used Pyrex glass for these tubes for mechanical reasons, although it is quite possible that other glass may prove more advantageous. We have preferred to use each section at a somewhat smaller voltage and to increase the number of

Fig. 1. Six-section tube, with potentiometer and typical shields unmounted.

sections rather than to design each section for operation at the limiting value of 250 or 300 kilovolts, although this no doubt can be done later even with small sections such as we are using. The essential points in the design of tubes are: (a) the subdivision of the whole tube into sections; (b) the uni-

Fig. 2. Fifteen-section tube.

form distribution of voltage between sections by means of a potentiometer or some other electrical circuit; and (c) electrostatic shielding of the sections outside of the vacuum. The type of potentiometer used is shown in Figure 1. The glass tube is filled with a weak solution of salt in water. The concentration of salt is adjusted by trial until the potentiometer connected

across the Tesla coil produces a measurable effect on the voltage, for example until it reduces the total voltage by one quarter or somewhat more. The taps of the potentiometer are connected to the successive electrodes of the vacuum-tubes. In operation the potentiometer is put inside the shields.

The type of shield used is also shown in Figures 1, 2, and 3. The 15-section tube, each section of which was $4\frac{3}{4}$ inches long, had shields $3\frac{3}{4}$ inches long, the diameter of each shield being about 8 inches. The spacing between shields was about 1 inch. Experience showed that shielding of bulbs at high potentials is quite necessary. This may apply only to the high-frequency alternating type of potential we are using.

Fig. 3. Fifteen-section tube mounted in steel tank showing shields in position; Tesla coil in place but oil pumped out.

As is seen in Figure 1 the connections to the electrodes were made through waxed joints. There was thus no question of an extremely high vacuum since the tube as a whole could not be baked. The electrodes themselves (copper) were prebaked at 950°C in a quartz-tube furnace. The tube was also torched with a gas flame while evacuated, before the electrodes were put in. Carbon-dioxide snow in alcohol was used on the trap for keeping down the pressure of Hg and other condensable vapors. No refrigerant was used during the first half-hour of pumping, in order to pump out most of the water-vapor. Liquid air on the trap obviously might be quite dangerous in case of an accident, since the tubes are tested under oil. As indicative of the rather low degree of vacuum required it may be of interest to mention that the 15-section tube withstood 1,000,000 volts without trouble only 4 hours after

it was assembled and the pumps started. This was without torching any of the glass parts.

An important point about bringing up a tube to a high voltage is "breaking in" as in the case of x-ray tubes on direct current or low-frequency alternating current. When a potential is first applied the tube may flash at one-half of the potential which it stands without puncture after it is broken in. Our procedure is to bring the potential up cautiously until the tube flashes. Then the potential is lowered until the flashing weakens appreciably. After a few minutes running or less the flashing disappears. The potential is brought up until the tube flashes again and the procedure is repeated. In cases where one of a set of bulbs shows bad flashing it is sometimes helpful to break this section in by itself. There is of course an approximate limit which a given size of bulb of a given design will not exceed. The potential which can be applied to the whole tube is however rather accurately equal to the potentials which may be applied to the bulbs separately. Thus the bulbs act independently. The "breaking in" procedure may at times be carried out safely by letting the tube flash and allowing it to rest for a minute or two. Then the potential is applied again. The flash is often weaker or absent. It seems that it is important to pump off the gases evolved during a flash. The "breaking in" of a tube is somewhat similar to the "breaking in" of oil described in the preceding article. The "breaking in" lasts, that is, if a tube is broken in one day it can be broken in to the same voltage on the next day in a much shorter time. At times no "breaking in" the next day is required. In all of these experiments we use the intermittent voltage-excitation by means of a stationary primary gap and direct current on the primary condenser described in the preceding article. It may be that the same tubes would be subjected to more danger if used on other and more continuous sources of potential.

It will be noticed that the increase in the potential applied to the 15-section tube over that used on the earlier 6-section one was not proportional to the number of sections and was especially out of proportion to the total lengths. It might be supposed that the use of tubes with many sections is disadvantageous. No such limitation was responsible for the insufficiently high voltage applied to the larger tube. One of the shields which was insufficiently well supported, fell on the tube and caused a puncture at the point of contact with the glass during the "breaking in" process. The flashing at 1,400,000 volts was not due to lack of additivity in the action of the bulbs, because the bulbs when tried separately flashed at about 100,000 volts per bulb. This relatively bad performance of the bulbs was in all probability due to partial contamination of the electrodes with mercury which occurred during an accident to the tube. The amount of work involved in taking the electrodes out, baking them, and putting them in again being considerable, the tube was repaired without removing the electrodes. Since the electrodes in the 15-section tube were larger and more nicely rounded than in the 6-section tube and since the bulbs in it were also larger there is every reason to expect at least one-sixth of 850,000 volts per section when care is taken

to have uncontaminated electrodes. It must also be mentioned that one of the 15 sections was not used because of a defect in the potentiometer at that section. The additivity of potentials which may be applied to the bulbs separately when they are connected in series seems thus to be demonstrated. We expect therefore that a 2,000-kilovolt tube can be constructed without serious difficulty.

So far we have tried hot cathodes in single-section rather than cascade tubes. The puncture-voltage was independent of whether a hot cathode was used or not. The evidence is that its use will not make the operation on the cascade principle more difficult.

(2) *Electrodeless tubes*—These have been mentioned by us in a previous publication.² Under proper conditions a spherical Pyrex bulb immersed in oil between electrodes does not puncture when a million volts is applied to the electrodes. The arrangement is shown in Figure 4. The exact conditions for successful operation of such bulbs are still not certain. The evidence

Fig. 4. Diagrammatic sketch showing the arrangement for electrodeless tube.

seems to be however that a partially electrically conducting-layer on the inside surface of the glass, in our case due to carbonized oil, is essential. The fluorescence patches of long duration observed with this type of bulb are quite similar to those occurring with the cascade-bulbs.

(3) *Miscellaneous experience*—Long tubes, with one electrode at each end put inside the Tesla, puncture readily. The high-frequency field produced by the Tesla is thus insufficient to prevent accumulation of charges inside the tube.

Sealed off commercial Coolidge tubes at times stand a higher Tesla voltage than would be expected from their behavior on direct current. This however is not always true. It was impossible in our experience to exceed 400 kilovolts without bad flashing. One 220-kilovolt deep therapy tube was punctured at 400 kilovolts.

An extraordinarily good vacuum is not essential in securing good operation of single-section tubes up to say 300,000 volts. Extreme precautions

² G. Breit and M. A. Tuve, *Nature* 121, 535 (1928).

with regard to vacuum technique do not suffice in our experience to bring about anything but very erratic improvements beyond this figure.

One quite definite type of failure is that shown by "straight" tubes, whether single or cascade, made by enclosing the electrodes in ordinary drawn Pyrex tubing of a diameter not much larger than that of the electrodes themselves, instead of in bulbs. Such a rigid design of tube would be mechanically very desirable, but 10-section and 20-section tubes made in this way have failed well under 500,000 volts, the glass wall shattering inward from longitudinal striae or bubbles in the glass without puncturing through to the outside. Violent flashing then limits the voltage which can be applied. The striae are usually invisible before the shattering takes place.

The authors take pleasure in recording their indebtedness to O. Dahl, whose assistance during a part of this tube-work has been invaluable, and again to J. A. Fleming for his support of the work.

ANODE SPOTS AND THEIR RELATIONS TO THE
ABSORPTION AND EMISSION OF GASES BY THE
ELECTRODES OF A GEISSLER DISCHARGEBY C. H. THOMAS AND O. S. DUFFENDACK
UNIVERSITY OF MICHIGAN

(Received September 23, 1929)

ABSTRACT

In a Geissler discharge containing H_2 , N_2 , CO, mixtures of hydrogen and the rare gases or mixtures of mercury vapor in the rare gases at pressures of 0.5 to 12 mm and electrode separation of 4 to 30 cm, the anode glow breaks up into a number of bright hemispherical spots, more or less symmetrically arranged when the polarity of a direct current discharge is reversed. Anode spots do not form in O_2 , A or Ne but faint spots form in He which contain a trace of H_2 . It is shown that one necessary condition for the formation of spots is the emission of gas from the surface of the anode. As many as 75 spots arranged in 5 concentric rings have been observed on an anode 34 mm in diameter. Conditions governing the number, size and duration of the spots have been determined. Spots formed on all the metals tried; Fe, Ni, Al, Cu, Hg and brass. The formation of anode spots has been used to prove that in a Geissler discharge between cold electrodes, the cathode absorbs gas and the anode emits gas at rates which are functions of the current density, gas pressure, kind of gas and electrode temperature. It is shown that the increase of the potential drop of a discharge with time, is due almost wholly to an increase in the gas content of the cathode, and that the potential drop immediately after starting a discharge is lowered by previously degassing the cathode by means of an induction furnace or by using this electrode as anode.

INTRODUCTION

ALTHOUGH hundreds of investigations have been carried out during the past fifty years on some part or other of the Geissler discharge, a complete understanding of the phenomena which occur therein is still lacking. Among these phenomena is the "clean up" or disappearance of the gas. It has long since been postulated that the electrodes absorb gas but in the past no direct proof of this has been given although the several explanations^{1,2,3,4} of the phenomena of cathode sputtering have as their bases the absorption of gas by the cathode or the existence of gas in it.

That certain gases diffuse through certain metals is shown by the diffusion of hydrogen through palladium. Yamada⁵ has shown by spectroscopic analysis that absorption of hydrogen in palladium produced a uniform expansion of the space lattices by 2.9 percent. He found no evidence that the absorbed hydrogen had reacted with the palladium.

Baum⁶ has made microphotographs of silver cathodes which had been used in a Geissler discharge of 3000 volts in which he found that gas molecules had penetrated to a depth of 1.5 mm.

In some recent experiments, one of the writers has had occasion to investigate an alternating current Geissler discharge in hydrogen. He found that during one half of the cycle of alternating current the discharge did not strike. During the succeeding half cycle, the discharge struck when the voltage had attained the sparking potential of the gas for the existing pressure-distance conditions. A check on the history of these electrodes showed that they were of the same metal and that they had been subjected to the same treatment except that a direct current discharge in hydrogen had previously been passed between them. The discharge struck with A.C. when the electrode previously used as anode in the D.C. discharge was negative.

This experiment shows that the use of an electrode as anode or cathode changes its sparking potential. Later in this paper, it will be shown that this difference in sparking potential was due mainly to a difference in the amounts of gas absorbed in each electrode. During the investigation of this difference in sparking potential, the anode spots appeared. The term anode spots is used throughout this paper to apply to the hemispherical bright spots which were more or less symmetrically arranged on the cathode side of the anode.

The appearance of anode spots has been previously reported by Lehmann⁷ who found them in a discharge in air in a tube of wide diameter, and by Mackay⁸ who found more elaborate patterns in helium. Neither author attempted any explanation of the formation of the anode spots.

OBJECT

In the light of this information, it seemed advisable to make the following investigations: (1) A determination of the cause of anode spots; (2) A study of their characteristics; (3) An application of the phenomenon of anode spots to the study of emission and absorption of gases by the electrodes of a Geissler discharge; (4) A study of the effect of gas absorbed in the electrodes on the potential drop of the discharge.

APPARATUS

The vacuum system consisted of the usual pumps, mercury cut-off and liquid air trap. The gas pressure in the system was determined by means of two McLeod gauges whose combined range extended from 30 mm to 2×10^{-5} mm of mercury. A gas storage and purifying system was connected by suitable stopcocks to the vacuum system so that either all parts could be evacuated to a high degree or purified gas could be admitted to the experimental tube.

Figure 1 is a diagram of the experimental tube most used. The tube proper was 63 cm in length and 6 cm in diameter. Electrical connections were made

to the movable electrode through a capillary glass tubing which supported it. By means of a magnetic force on a cylinder of soft iron which was fastened to this capillary shaft, the one electrode could be moved through a distance of 30 cm. The electromagnet for moving this electrode was mounted on a screw device which permitted a slow regular movement of the electrode.

Electrodes of several sizes, shapes and thicknesses were used as well as similar electrodes with different degrees of polish. In several cases, extreme care was taken that no foreign material touched the electrode surface except the steel tool with which it was turned down. The electrodes were supported on glass stoppers in such a way that only one half inch of metal was exposed behind each electrode. Thus the distortion of the electric field was reduced to a minimum. The glass stoppers were ground to fit another tube of the same length as the first but of a diameter 4 cm larger than the latter. A third glass stopper which supported a spiral tungsten filament was interchangeable with the stopper which carried the fixed cold electrode.

A direct current motor-generator set supplied the potential which was regulated by changing the resistance in the circuit of the field exciter. The voltage across the tube was measured on a Jewell voltmeter of range 0 to 500

Fig. 1. Experimental tube.

volts. This voltmeter was equipped with suitable external resistances by means of which the voltage range could be extended up to 2000 volts. A resistance of 3000 ohms was placed in series with the experimental tube. By means of a reversing switch the direction of the discharge through the experimental tube was easily changed.

PROCEDURE

Whenever any appreciable sputtered material appeared on the inner walls of the tube or when a change of electrodes was made, the tube was disassembled and cleaned with aqua regia. Subsequently, the tube was mounted in its usual position and the glass stoppers were turned until the electrodes were parallel and symmetrically placed as judged by the eye after which the ground glass joints were sealed with De Khotinsky cement. The necessary precautions were taken for the removal of water vapor and occluded gases and for the exclusion of mercury vapor from the tube.

Extreme care was exercised in order to obtain pure hydrogen, carbon monoxide, argon, neon and helium. However, in no case was it possible to remove all traces of hydrogen from helium, possibly because the system and tube had previously been used for hydrogen.

The electrode separation was determined by measuring the relative position of the soft iron cylinder on the shaft which supported the movable

electrode. By this method the electrode separation could be easily determined within one half a mm regardless of the condition of the discharge tube proper.

When the gas, tube, and electrodes were properly prepared, the gas was admitted slowly to the tube through a liquid air trap until the desired pressure was attained. In the cases in which the effects of complete degasification of electrodes were investigated, the discharge was set up in the tube within a few seconds after the gas was admitted to the tube in order that the electrodes might have little time for absorption of the gas.

The ordinary procedure was to allow the one electrode to serve as cathode for a given time at a given current. This is called the period of "soaking" during which the cathode absorbed gas through positive ion bombardment. The polarity of the electrodes was then reversed so that the electrode which had been soaked as cathode now became the anode. Anode spots then formed on the anode if the pressure-electrode distance conditions were suitable. The discharge was then maintained at a constant current or potential during the period of the existence of these spots on the anode.

As soon as the last spot disappeared from the anode, the discharge was stopped, since it is assumed that for a given current, the spots disappeared when the rate of evolution of the gas from the anode had decreased to a critical value. Within a few seconds after the discharge was stopped, as mentioned above, the process was repeated. Thus a series of observations which showed the effects of the soaking of the cathode on the characteristics of the anode spots were obtained.

It was observed early in this investigation that the number of spots which appeared under similar conditions of current, pressure, etc., was different depending on whether the current was increased or decreased in order to obtain the desired value. This was to be expected since the spots often formed in patterns such that a considerable change in current was necessary to change the pattern. It was necessary, therefore, to use the same applied potential difference at each closing of the switch in order to obtain consistent results in the number of spots which were formed on the anode.

Throughout the work, particular attention was paid only to the one electrode for which the gas content and previous treatment had to be known at all times.

Photographs were taken at an angle of 30 degrees with the axis of the tube. Sometimes difficulty was encountered in obtaining a satisfactorily stationary pattern. The photographs of the spots which are presented in the succeeding parts of this paper were obtained with an exposure of one-fifth second on a Voigtlander camera which had an F 4.5 lens.

RESULTS

Presentation and discussion of photographs: The photographs presented in Figure 2 were chosen because they show the relative difference in the size of the spots. In pictures *a*, *b*, *c*, and *d*, the electrodes were 41 mm in diameter, while those in pictures *e*, *f*, *g*, and *h* were 34 mm in diameter. In picture *g*, the

spots were rotating rapidly under the influence of their own magnetic field. Picture *h* which was taken perpendicular to the axis of the tube shows the hemispherical form of the spots and their appearance back of a striation.

Fig. 2. Typical patterns of anode spots.

The experimental conditions for the patterns which are presented in Figure 2 are given in Table I.

TABLE I.

Pattern	Kind of gas	Gas pressure in mm Hg	Electrode separation in cm	Potential drop in volts	Current in milliamperes
<i>a</i>	nitrogen	0.41	10.5	825	17
<i>b</i>	hydrogen	2.25	16.9	880	125
<i>c</i>	hydrogen	5.8	12.3	625	275
<i>d</i>	hydrogen	3.3	14.7	881	180
<i>e</i>	(argon 90%) (hydrogen 10%)	9.0	10.8	690	240
<i>f</i>	hydrogen	3.1	13.2	920	160
<i>g</i>	hydrogen	3.35	14.3	1240	200
<i>h</i>	hydrogen	2.55	18.3	902	85

Results for different gases. Anode spots did not form in any gas when the electrodes had been sufficiently degassed provided that mercury vapor was excluded from the tube and that the discharge was set up within two minutes after the admission of the gas. In general, anode spots formed in hydrogen, nitrogen, carbon monoxide, air, and in certain gas mixtures. Spots did not form in oxygen, pure argon or pure neon. The formation of very weak spots in helium which contained a trace of hydrogen will be discussed later.

In a discharge in hydrogen, the spots formed over a gas pressure range of from 0.6 to 12 mm. The gas pressure limits varied with different gases; but in all gases, the lower pressure value was limited by the possible electrode separa-

tion and the higher pressure value was limited by the limit of the current which was available from the generator. Hydrogen was different from other gases in that, for a given pressure, the spots formed over a comparatively wide range of electrode separation which in some cases was as much as 20 cm. When striations were present in the hydrogen discharge, the spots appeared when the anode was placed in the dark space between the striations. The spots disappeared and reappeared as the anode was moved through the bright part and the dark part of the striations respectively. In case the configuration of spots was made up of several rings, the outside ring disappeared first as the anode was moved through a striation which, for the smaller electrodes, was conical in shape.

When a well-degassed electrode was allowed to remain in hydrogen for a few minutes, spots which lasted as long as a second or two were formed at the first passage of the discharge. This observation shows that the metal of the electrodes absorbed hydrogen even in the absence of an electric field. Degasification of the electrodes by means of the induction furnace after they had been used in hydrogen gas was almost as difficult as was the degasification of new electrodes.

The anode spots formed easily in nitrogen over a pressure range of 0.4 to 14 mm of mercury for available electrode separation and current limits. In nitrogen, however, the spots formed only at the beginning of the positive column within a range of two cm at most. As the anode was moved farther into the Faraday dark space, the spots gradually disappeared. When the anode was moved farther into the positive column, the configuration of spots became unstable and finally merged into the positive column. This peculiarity of limitation of the formation of spots to the neighborhood of the beginning of the positive column in nitrogen and other gases which gave a strong positive column make it impracticable to carry out as extensive investigations in these gases as in hydrogen.

Anode spots formed very readily when the anode was placed near the beginning of the positive column of a discharge in carbon monoxide. The spots which were greenish white in color in this gas, formed over a pressure range of 0.4 to 15 mm of mercury for the electrode separation and current limits of the apparatus. For a given period of "soaking" of the cathode in carbon monoxide, the spots lasted much longer than in either hydrogen or nitrogen. Moreover, degasification of electrodes, subsequent to their use in carbon monoxide discharge, was much more difficult than that of electrodes used in hydrogen or nitrogen.

No anode spots were formed in pure oxygen under any conditions. In mixtures of oxygen and carbon monoxide, spots did not form until the carbon monoxide content of the mixture had reached about 30 percent. Then anode spots which were characteristic of carbon monoxide were formed.

An electrode was "soaked" to saturation in carbon monoxide. The carbon monoxide was then removed from the tube and oxygen was substituted. Under these conditions, spots which were characteristic of carbon monoxide formed on the anode which was then full of carbon monoxide. Such spots

lasted for three or four minutes. This observation is direct proof that the anode spots are formed by gas being evolved from the anode under electron bombardment. The previous observation that 30 percent carbon monoxide in oxygen was necessary for anode spot formation precluded any possibility of the formation of these spots by any small amount of residual gas.

Anode spots were not formed in pure argon or pure neon. In these gases there was a tendency for the positive column to separate into two or more parts which rotated with respect to the axis of the tube. These streamers ended in bright spots on the anode which, however, were not of the same nature nor of the same origin as the anode spots now under investigation.

In argon, neon, and helium, the presence of mercury vapor given off from a mercury surface in the tube permitted the formation of bright anode spots. Bright anode spots also were formed when ten and five percent hydrogen was present in argon and neon respectively. Since no arrangement was made in the present apparatus for mixing and circulating the gases in the discharge tube, the above percentages may be somewhat in error. However, they are of the correct order of magnitude.

When the helium was apparently pure except for a small trace of hydrogen, very weak yellow anode spots appeared. These weak spots in helium were much larger than those for a corresponding pressure in another gas. However, these spots were symmetrically arranged and had all the characteristics of true anode spots. Bright anode spots appeared on the anode in a discharge in helium to which two tenths of one percent hydrogen had been added.

Effect of the metal of the electrodes. The effect of the metal on the formation of anode spots was studied only qualitatively. Anode spots formed on electrodes of iron, nickel, copper, aluminum, and brass. Electrodes of iron were used almost entirely for the quantitative study because its rate of sputtering was low. However, electrodes of nickel produced no noticeable change in the characteristics of the spots from those observed on iron electrodes. The thickness of the electrodes was found important only insofar as it affected the change of temperature of the electrodes.

The anode spots were not symmetrically arranged on the anode when impurities were present on the surface of the anode or when a new electrode was used as anode without previous degassing. However, the use of a new untreated electrode for a few minutes as cathode put it into such a condition that a symmetrical pattern of spots was formed when it was subsequently made anode.

The use of a barium coated electrode as cathode resulted in a decrease in the potential drop across the tube. As cathode it gave a symmetrical arrangement of spots on an uncoated electrode used as the anode; but when it was used as anode the spots were very unsymmetrically arranged, due most probably to the non-uniformity of the barium oxide layer.

Unsymmetrically arranged anode spots were formed on a carbon anode. The effects of local heating produced bright anode spots on the carbon. The carbon electrode could not be outgassed with the induction furnace. More-

over, the surface of the carbon could not be made to absorb gas uniformly by reversing the direction of the current because the discharge from the cathode was concentrated on several small areas on the carbon surface of the sleeve of this electrode. On the whole, the carbon electrode was unsatisfactory both as a cathode and as an anode. Nevertheless, anode spots were formed on its surface from the occluded gases.

Faint anode spots which were symmetrically arranged appeared on the surface of an anode of mercury in hydrogen and in the rare gases.

Rotation of the anode spots. The spots were seldom stationary on the anode for any length of time. Under the influence of the magnetic field which was set up by the passage of the current through the tube, the pattern of spots rotated with respect to the central axis of the tube, sometimes in a clockwise direction and at other times in a counter clockwise direction. The angular velocities of the spots in the various rings were not the same, the outer ring having the largest. At times the direction of rotation in two concentric rings was opposite. An increase in the distance between the electrodes increased the tendency for rotation of the pattern.

A solenoid placed coaxial with the tube, and away from the anode, so that a part of the field was radial to the electrode, could change the rotational velocity of the spots in the rings and even reverse the direction of rotation. When a solenoid was placed perpendicular to the axis of the tube in the immediate region of the anode, the configuration of spots was deformed by the magnetic forces so that the spots then appeared in a deformed circular pattern which also rotated rapidly during the application of the magnetic field of the solenoid. An unstable and unsymmetrical pattern of spots always formed when the walls of the tube in the neighborhood of the anode were badly sputtered.

Size and shape of electrodes. Circular electrodes of 41 mm and 34 mm in diameter were used. Under the same experimental conditions, the size of the spots was larger on the larger electrodes.

The use of a small spiral incandescent tungsten cathode did not destroy the symmetry of the anode pattern of spots when this cathode was placed on the line of the axis of the anode.

That the pattern of spots was governed primarily by the shape of the anode was proved by the use of a circular cathode and a triangular anode on which the spots formed in a triangular pattern which contained as many as four distinct triangles with their sides parallel to the edges of the anode. When the electrodes were placed so close that the form of the cathode influenced the field at the anode the spots on the anode were equally spaced on the sides of the triangles, but when the electrode separation was increased to some extent, the spots, except those forming the vertices of the triangles, tended to concentrate toward the middle of the sides of the triangles, but even then the form of the triangle was not destroyed.

When the electrodes were not parallel, an asymmetrical arrangement of spots always resulted. Under these conditions, the angular velocity of a spot was not uniform. Its angular velocity was greatest where the separation of the electrodes was greatest.

When the electrodes were parallel their centers were not on the same horizontal lines. The pattern of spots was displaced from one edge of the anode.

Size and intensity of anode spots. In general the size of the spots increased with an increase in the gas content and temperature of the electrode, with a decrease in the gas pressure, with an increase in the size of the electrode, and slightly with a decrease of the distance between the electrodes. The size of the spots definitely decreased with an increase in current and voltage. It also decreased with an increase in the age of the spots, although, for constant potential, the current decreased during their life.

Figure 3 is composed of two photographs of patterns of anode spots in hydrogen at 2.6 mm pressure and electrode separation of 17.2 cm. The pattern on the left was formed by 210 milliamperes at 1300 volts and the pattern

Fig. 3. Change of number of spots with change in current and voltage.

on the right by 30 milliamperes and 725 volts. These photographs show the change in the number and in the intensity of the spots with a change of current and voltage.

The change of the size of the spots with the change of temperature of the anode is shown in Figure 4. These photographs were taken as a discharge

Fig. 4. Change in size and number of spots with change in temperature of anode.

passed through hydrogen at a pressure of 2.45 mm between electrodes separated 17.7 cm. The picture on the right is that of an anode which was saturated with gas by means of soaking it previously as cathode. This picture was taken after the electrode had cooled to room temperature, with a current of 115 milliamperes at 1120 volts. The picture on the left was taken while the anode was still red hot from its previous use as cathode, with a current of 115 milliamperes and 1100 volts.

The intensity of the spots increased with an increase in current and voltage. To a small degree, it depended on the kind of gas. Hydrogen gave brighter spots than nitrogen. The intensity was quite high when a rare gas was mixed with hydrogen or mercury vapor.

Factors which influence the number of spots. The number of spots which appeared in the pattern on the anode increased with an increase of pressure, with an increase in current, with an increase in the amount of gas in the surface of the anode up to a saturation value, and slightly with an increase of distance between the electrodes. An example of the increase in the number of spots with an increase in current and voltage is given in Figure 3 above. The number of spots decreased with an increase of the temperature of the anode within certain limits. An example is given in Figure 4.

The same pattern of spots was obtained after a thirty second period of soaking of the electrode as when the electrode was soaked ten minutes provided that the temperature change in the electrode during this latter period was not over two hundred degrees. This indicates that the condition of the surface layer or near surface layer governed the number of spots and that this layer quickly reached saturation.

Mention has already been made of the observation that spots were formed from gas which was absorbed by mere contact with the metal. The following experiment showed that spots were also formed by gas which diffused to the surface of the anode. The cathode was soaked with hydrogen gas until saturation was reached, then it was used as anode until the spots disappeared. Immediately afterward the tube was evacuated to a pressure less than 2×10^{-4} mm at which pressure it remained for forty-eight hours. At the end of this period, hydrogen was again passed into the tube until a pressure of 3.3 mm was reached. Forty spots in four rings were present when the discharge was established within a few seconds after the gas was admitted. At the end of 25 seconds the number of spots had decreased to 30 in three rings. The remainder of the spots disappeared simultaneously at 30 seconds.

The large number of spots which appeared under the above conditions and the short life of the spots indicate that the gas, which had penetrated to a considerable depth in the electrode diffused to the surface or to the layers immediately underneath the surface. Since a considerable amount of gas was given off from the anode only during a thirty second period, one may conclude that the gas which diffused to the surface, was held there

by the molecular forces of the metal. Since no similar effect was observed when a degassed electrode was treated in a similar manner, it is not probable that these spots were formed from hydrogen absorbed while the electrodes were subjected to the low gas pressure given above.

Application of the phenomenon of anode spots to the study of the rates of absorption and emission of gases by the electrodes of a Geissler discharge: Let us assume that the cathode of a direct current Geissler discharge absorbs gas under the influence of positive ion bombardment at a rate which is a function of the number and energy of the positive ions which strike and of the gas content of the cathode at that particular moment. Let us further assume that the anode emits its absorbed gas under the influence of electron bombardment at a rate which is a function of the velocity of the electrons at the moment of striking, of the number striking, of the gas content of the anode, and of the kind of gas.

Fig. 5. Life-soaking curves for different soaking currents.

In order to test the validity of the above assumptions a series of experiments was carried out in hydrogen. Typical results are given in Fig. 5. The lower curve was obtained by subjecting the cathode to soaking in 3mm of hydrogen with a current of 20 milliamperes for different periods. At the end of each of these periods of soaking, the direction of the discharge was reversed and a current of 110 milliamperes was passed through the discharge until the last spot had disappeared from the anode. The lower curve of Figure 5 shows that, with a soaking current of 20 milliamperes, the life of the spots approached a constant value with a soaking period of 5 minutes. However, when a soaking current of 80 milliamperes was used the life of the spots was relatively longer as shown in the upper curve.

We believe that the differences in the lives of the spots for different soaking currents were due to differences in the rates of the absorption and in the total amount of gas absorbed. This difference in absorption was due to the difference in the temperature of the cathode during positive ion bombardment

and to the difference in the energy of the impinging positive ions under the two conditions.

Many similar curves were obtained in hydrogen with both the small and the large experimental tubes. The rates of absorption and emission of hydrogen changed with the change of conditions in the electrode. However, for a series of runs on the same day, the same type of curves was obtained. It was not possible to retrace the curves backwards because of a change in the temperature of the electrode in the long periods of soaking. For soaking currents between 20 and 80 milliamperes the curves fell between those given in Figure 5.

Since the charge on the walls of the tube influences the electric field at the anode and since the ratio of the random current to the drift current in the tube governs the anode drop, it was deemed advisable to investigate the effect of the diameter of the tube on the anode spots. To this end a tube of 10 cm was substituted for the tube of 6 cm diameter. The use of the larger tube resulted in a greater stability and uniformity of the pattern of the spots, less rotation of the spots and a longer period of use before cleaning was necessary. However, no appreciable difference appeared in the life-soaking curves which were obtained from the different tubes when the walls of the tubes were equally free from sputtered material. It was to be expected that a greater electrode separation would be required for the larger tube, because the length of the negative glow increase with an increase in the diameter of the tube.

It was possible to obtain curves as those given in Figure 5 only in hydrogen because in all gases having a strong positive column the change in the potential drop across the tube with the change in the gas content of the electrodes altered the position of the beginning of the positive column to such an extent that the anode was soon out of the narrow region in which the formation of anode spots was possible. However, in the case of carbon monoxide gas, the anode was moved through a small distance in order to keep it in the region of the anode spots. This method showed that the life of the spots for carbon monoxide, for a given amount of soaking, was considerably longer than that of hydrogen for similar soaking. This observation is only qualitative because the potential drop across the tube changed with the change in the distance of electrode separation.

Figure 6 contains the life-soaking curves for the same electrodes under the same conditions except that the curves were taken on consecutive days in the order given in the figure. Curve I, was obtained with new electrodes which had been carefully degassed by heating in vacuo by means of the induction furnace. Between the time of obtaining curves I and II, a discharge was maintained in the tube for short periods which totaled four hours after which the electrodes were again degassed by heating in vacuo. A similar procedure took place between the time of taking the data given in the consecutive curves of Figure 6. These curves show that the life of the spots increased with the use of and the degassing of the electrodes. On the assumption that a certain rate of evolution of gas from the anode is neces-

sary for the formation of anode spots, these curves show that the anode evolves gas for a longer time above that rate when the electrode is used in a discharge and is subsequently degassed.

In order than an electrode, under constant current conditions, evolve gas above a certain rate for a longer period, it must contain a greater amount of

Fig. 6. Life-soaking curves showing effect of aging of electrode.

gas to begin with or the rate of evolution of gas must be more gradual or both conditions must be fulfilled. For this we give the following explanation.

It is certain that some of the gas ions which are driven into the anode structure by considerable electrical force are more difficult to remove than are the molecules of the original occluded gas. Hence, degassing by means of heating

Fig. 7. Life-soaking curves for different electrode separations.

in vacuo may not be so efficient in removing such gas molecules. Therefore, the electrode may contain more gas to begin with even after the same period of degassing than it did before it was used so much as cathode. On the other hand, the spacing of the molecules of the metal may be so changed by use and subsequent degassing, that the hydrogen molecules will then be absorbed more readily as they strike the cathode in the form of positive ions. Also they may penetrate deeper into the metal of the cathode.

Experimental evidence, which supports this hypothesis, is given by Yamada⁵ who found that absorption of hydrogen in palladium resulted in a uniform expansion in the space lattices and by Baum⁶ who found that hydrogen ions under the influence of 3000 volts not only penetrated a silver cathode to some distance but that they also produced fissures in the crystal structure of the metallic electrode.

The life soaking curves which are presented in Figure 7 were obtained from data in which the experimental conditions except the change in electrode separation were kept constant, as nearly as possible. These curves show that the life of the spots increases with an increase in the electrode separation. This increase of the life of the spots with increase of electrode separation was not due to temperature increase or aging effect of electrodes because the data for the curve at 20 cm were obtained immediately after that used in the curve at 25 cm.

Since the electrode contained approximately the same amount of gas in both cases at the end of similar periods of soaking, and since the number of electrons striking the anode was also the same, this difference in the life of the spots for different electrode separations must have been due primarily to a difference in the velocity of the electrons at impact on the anode by which the rate of evolution of gas would have been different.

This change in the velocity of impinging electrons could have been produced by a difference in the electric field depending on the position of the anode especially if it was placed near the beginning of the positive column. Moreover, a change in the anode drop of potential may produce a greater change in the energy of impact of an electron on the anode than that which corresponds to a change of V in the relation $eV = 1/2 mv^2$. For instance, if the anode drop of potential is just greater than the ionizing potential of the gas, some of the electrons will make ionizing collisions with the gas molecules in the region of anode space charge, and will thus lose most of their energy. Such electrons will then strike the anode with much less energy than that of the electrons which make only elastic collisions with molecules because their velocities are below that which corresponds to the velocities necessary for ionization or excitation of the gas molecule.

Change of potential with the change in the gas content of the electrode. In Figure 8 are given the time-voltage curves during the life of the anode spots for a constant current of 110 milliamperes in hydrogen at 3 mm pressure and electrode separation of 22 cm. The anode in the discharge from which the data for these curves were taken was soaked at 40 milliamperes for the different periods given in this figure. These curves show that the anode spots disappeared in each case at approximately the same voltage. When the experiment was continued beyond the time of the disappearance of the spots the potential drop approached a constant value of which there is some evidence in these curves. (The curves in the Figure 9 show this more plainly.) We believe that the constant potential drop was determined by the conditions in the tube reaching a state of equilibrium, that is, the change in the gas content of the electrodes must have reached a steady state. These curves

also show that, at least within given limits, the potential drop, immediately after the initiation of the discharge was lowered by an increase in the soaking period of the cathode. Each of these curves corresponds to the determination of one point of the life-soaking curve such as given in Figure 6.

The differences in the potential drop for the discharge as shown in these curves were due almost entirely to different amounts of gas in the electrodes. Different amounts of gas were obtained in each electrode by varying the time of reversal of the current during which the cathode absorbed gas and the anode emitted gas. Degassing the cathode by means of an induction furnace resulted in a lower maintaining potential at the beginning than that given in curve VI of Figure 8.

Fig. 8. Time-voltage curves during life of spots.

That the differences in the maintaining potential which are evident in the several curves and in each single curve at different times, were due almost wholly to the processes at the cathode was proved by the following experiment. Two new iron electrodes *A* and *B* were degassed in vacuo by an induction furnace to an equal degree. Then electrode *A* was made cathode and electrode *B* anode in a discharge of 100 milliamperes in hydrogen at 2.8 mm pressure. The variation of the voltage with time is given in curve I, Figure 9.

Since both electrodes were degassed to begin with most of the change in potential difference was due to absorption of gas at the cathode since electron bombardment could free few gas molecules from the already degassed anode.

Upon reversal of the direction of the discharge at the end of three minutes, results were almost identical with those given in curve I although in this case

the cathode was a degassed electrode but the anode contained gas as a result of previous use as cathode for three minutes. Thus we found that degassed cathode and anode produced the same time voltage characteristics as a degassed cathode and a gas filled anode. From this we conclude that the evolution of gas from an anode under electron bombardment has little or no effect on the potential drop of the discharge.

Subsequently, electrode *A* which contained some gas was made cathode and the results given in curve II of Figure 9 were obtained. The main difference in the curves I and II is a higher starting potential difference when the cathode contained some gas. The irregularity of curve I between 60 and 100 seconds is typical of the curves obtained with new electrodes which were degassed by the induction furnace. We believe the change in potential to

Fig. 9. Time-voltage curves with new electrodes.

be due to evaporation of impurities from the surface of the cathode, impurities which were brought to the surface of the metal during the first heat treatment.

DISCUSSION OF RESULTS

Summing up the behavior of the anode spots, we see that their formation and existence must depend on the joint action between the gases released from the anode and the electron stream to the anode. From their magnetic behavior and from their dependence on the distance between the electrodes, we deduce that they must be the manifestations of a splitting up of the electronic current into discrete and more or less stable "rays" or current-beams. Also, since their life was, within limits, proportional to the length of time the electrode had previously been used as cathode, since their number decreased with the time that the electrode was used as anode, since no spots formed on a well outgassed anode, and since spots having the color characteristic of carbon monoxide formed in a discharge in oxygen on an anode previously

soaked in carbon monoxide, we infer that gas must escape from the anode in order that the formation of electron beams and their resultant anode spots be possible.

On the assumption that one necessary condition for the formation of anode spots is the evolution of a certain amount of gas from the surface of the anode when it is subjected to electron bombardment, we shall now give an explanation of the formation of the anode spots.

When no gas is liberated by the anode, the electrons form a space charge sheath which limits the more intense part of the field to within a short distance of the anode,⁹ of the order of a few millimeters at the pressure used. Outside the sheath the electric intensity is so small that the drift velocity of the electrons due to the field is not sufficient to keep them in relatively straight paths parallel to the axis of the tube, and they scatter by successive collisions with the gas molecules until the slowly drifting stream fills the cross section of the tube.

When these electrons enter the sheath, their increased speed causes them to fall to the anode in nearly straight lines. It is, then, in this sheath, where the field is large, that there is any possibility of formation of electron beams; and the chance of their formation increases as the sheath increases in thickness.

If, now, gas is emitted from the anode, the molecules will either already be ions, or will soon become ions by collision with electrons, and these ions will partially neutralize the electronic space charge, thus increasing the sheath thickness and decreasing slightly the anode fall of potential, and therefore making the formation of beams more probable. Inasmuch as one positive hydrogen molecular ion neutralizes the space charge of three hundred or more electrons a small quantity of gas from the anode will cause a large change in sheath thickness, and under these conditions the electrons will move in straight paths for a centimeter or more before striking the anode.

Only a small portion of the current will be concentrated in the spots, for the gas will scatter many electrons to the other parts of the anode. These rays will be the favored paths, however, and the fastest electrons, those which have suffered few collisions, will travel therein. These faster electrons will create more ions than the other scattered ones, and so, a short time after the discharge is started, these beams will act as separate phenomena superimposed on the back-ground of scattered electrons, having their own potential distribution, their own motions, and their constant current density. This current is probably due predominantly to the ions created by the original electron beam in the gas coming from the anode. For this reason, and because the gas from the anode increases the sheath thickness, it is probable that the number of spots or beams present is proportional to the amount of gas evolved by the anode.

Since anode spots form only at the beginning of the positive column in gases which have a strong positive column and since they form before the first striation and in each dark space between successive striations when

⁹ Langmuir, *Gen. Elec. Rev.* 27, 767 (1924).

striations occur in the tube, it is now necessary to show why the spots form on the anode when it is placed in these positions.

Langmuir⁹ explains how an electron sheath around an anode may be broken down suddenly, through its neutralization by positive ions which are formed in the space charge sheath, to such an extent that the anode drop falls discontinuously to a lower value. He found that, when breakdown occurred, the anode glow usually appeared in the form of a sharply defined hemispherical region several times more luminous than the surrounding region. In this explanation, he assumes that very few gas molecules are present in the electron space charge sheath so that only a small fraction of the electrons which pass through this sheath make ionizing collisions. He further assumes that the gas molecules which are present in this sheath come into the sheath from the region on the outside of the anode sheath.

However, it is apparent from his theory that the breakdown of the electron sheath will be brought about the more easily the greater the concentration of gas molecules in the space charge sheath since a larger percentage of the electrons then make ionizing collisions with the gas molecules in their passage through the space charge sheath. Thus we see that the emission of gas from the anode will assist in the neutralization of the space charge sheath, which results in an increase in its thickness and a decrease in the total anode drop of potential.

It is evident from the preceding discussion that the electron space charge sheath will increase in thickness or breakdown (in the sense as used by Langmuir) more easily in the regions where the field is small. Therefore, the anode spots, whose appearance is due to the increase in the thickness of the electron space charge sheath of the anode or to its breakdown, will form when the anode is placed in the region at the beginning of the positive column where the electric field has not yet attained the maximum value of the positive column. In the dark space regions between striations, the field is again small. Therefore, these dark space regions between striations will also be favored regions for the formation of anode spots.

A field which is below that necessary for the production of an anode glow by ionization is excluded from this consideration. Consequently, the region of the Faraday dark space is excluded because there the anode drop of potential is too low to produce ionization, so that one would not expect the formation of anode spots.

We believe that anode spots do not form in oxygen because the oxygen ions, on striking the cathode, react with the metal of the cathode to form stable compounds which are not decomposed under subsequent electron bombardment of the anode.

Since the rare gases, helium, neon, and argon do not react chemically with any substance under any condition, and since very little gas was evolved in the degasification of electrodes subsequent to their use in these rare gases, we infer that these gases are not absorbed by the metal of the electrodes in amounts which are capable of producing anode spots. We believe that very weak yellow anode spots were formed in helium which contained a trace of

hydrogen whose presence could be detected by means of a direct vision spectroscope because the anode space charge sheath was not sufficiently broken down by the presence of a few hydrogen ions to permit the formation of bright spots.

Considering the effects of absorption of hydrogen by an electrode in a mixture with the rare gases and the production of hydrogen ions by collision with excited atoms, we have been able to explain, to our own satisfaction, the formation of bright anode spots when 10 percent, 5 percent and two tenths of one percent of hydrogen is present in argon, neon and helium, respectively.

When mercury is present in the discharge tube, sufficient mercury molecules are present on the surface of the anode to bring about the formation of anode spots in each of the rare gases. Anode spots appeared under similar conditions of the gas as those described by MacKay⁸ who photographed the spots in a discharge in helium containing mercury vapor. MacKay reports in the same paper the formation of spots of similar nature when mercury was excluded from the discharge tube. In that event, the helium which he used must have had, as impurity, hydrogen to the extent about two tenths of one percent. From the nature of the spots formed when a trace of hydrogen was present in the helium, it is doubtful if anode spots will be formed at all in pure helium.

Since anodes spots are formed by beams of electrons we would expect these beams to be influenced or even rotated by the application of a suitable external magnetic field. We offer the following explanation for their rotation in the absence of a magnetic field.

The drift current approaches the anode in the form of a frustum of a cone rather than in the form of a cylinder so that there will be present in the tube a small resultant radial magnetic field which will be sufficient under certain conditions to set the whole pattern in rotation. As the electrodes are separated farther apart, the influence of the electrodes on the drift current will be less, so that some of the drift current will approach the anode at a greater angle with the axis of the tube in a manner which may be likened to the change of the lines of electric force. Then the radial component of the magnetic field will be greater so that the angular velocity of the pattern will be increased.

In order to explain the change of sense of rotation of the pattern, the rotation in the opposite sense in consecutive rings and even the formation of a stable pattern, one would have to consider, in addition to the component of the magnetic field already discussed, the magnetic field set up by the diffusion of the electrons to the walls.

Since a given rate of emission of gases from the anode is necessary for the formation of anode spots, this phenomenon can be used as a measure of the rate of emission of gas from the anode and indirectly as a measure of gas absorption by the cathode. By the application of this method, we find that a cathode absorbs certain gases in proportion to the time of soaking up to a certain saturation value which is determined by the current and voltage of soaking, the temperature of the cathode and the previous treatment of the

electrode. We also find that the anode emits both absorbed and original occluded gas when it is subjected to electron bombardment.

Finally, in consideration of the evidence which follows, we believe that the absorption of hydrogen gas by the cathode of a Geissler discharge increases the potential drop across the tube until saturation of the cathode with gas is reached.

1. The potential drop increased with time until it reached approximately a constant value which depended upon the current density and the temperature of the cathode, in almost the same way that the life of the anode spots increased with an increase in the period of soaking of the cathode for a similar current density.

2. Degassing an electrode previous to its use as cathode either by having it serve as anode in a Geissler discharge or by heating it in vacuo with induction currents resulted in a decrease in the potential necessary to maintain the discharge for a short time after the discharge had struck. This decrease was a function of the amount of gas which had been emitted from the electrode in degassing.

3. After a discharge had been discontinued for a time, the potential drop was always lower at the second initiation of the discharge than it was just previous to the time of its discontinuation.

4. Although the cathode contained different amounts of gas to begin with in different experiments under the same conditions, the potential drop approached the same limit in each case as the cathode approached saturation in absorption of gas.

5. Experiments under identical conditions, except that in one case the anode was full of gas and in the other it was thoroughly degassed, gave almost identical time voltage curves. This we take to be good evidence that the emission of gas from the anode has little or no effect on the potential drop of a discharge.

We wish to express our indebtedness to L. B. Headrick and Dr. P. M. Morse for helpful suggestions in this work.

ELECTRON VELOCITIES IN A HIGH FREQUENCY DISCHARGE IN HYDROGEN

BY CHARLES J. BRASEFIELD
UNIVERSITY OF MICHIGAN

(Received November 20, 1929)

ABSTRACT

A high frequency discharge in hydrogen was obtained by applying undamped high frequency voltages to the movable external electrodes of a cylindrical discharge tube. The mean velocity of the electrons in the discharge was determined from the ratio of the densities of certain singlet and triplet lines of the molecular spectrum of hydrogen. It was found (1) that the electron velocity increases as the voltage between electrodes is increased, the gas pressure and the frequency of oscillation being constant; (2) for a given voltage between electrodes, the electron velocity is, in general, greater the longer the wave-length of oscillation; (3) the electron velocity decreases as the pressure is increased. The paper concludes with a discussion of the mechanism of the high frequency discharge in which an explanation of its behavior is proposed.

INTRODUCTION

IN THE study of any sort of gaseous discharge, one of the more important items of interest is the mean velocity of the electrons in the discharge and its variation under different conditions. The high frequency discharge with external electrodes is a very peculiar type of gaseous discharge. Studies have been made of numerous characteristics of this discharge, such as the striking and maintaining potentials¹ and the conductivity² but to the writer's knowledge no one has succeeded in determining the mean electronic velocity in the discharge. As a matter of fact, it would appear to be extremely difficult, if not impossible, to make such measurements by the ordinary method applied in arcs and glow discharges, namely, the Langmuir exploring electrode method. It has been suggested³ that the mean electron velocity in a high frequency discharge in hydrogen might be determined from the ratio of the densities of certain singlet and triplet lines of the molecular spectrum of hydrogen. This method has been employed with more or less success in the present work.

APPARATUS

To produce the high frequency oscillations, two U. X. 852 75-watt tubes were used in push pull in an ordinary Colpitts circuit, which is shown diagrammatically in Fig. 1. The plate voltage was supplied by a 2 KW, 3000 volt transformer, T_1 , and measured by an electrostatic voltmeter, V .

² H. Steinhauser, Zeits. f. Physik 54, 788 (1929).

³ C. J. Brasefield, Phys. Rev. 34, 437 (1929).

One quarter ampere fuses, F , protected the plates from overloading. The radio frequency chokes, $R.F.C.$, were made of #30 B. & S. copper wire, $S.C.E.$, wrapped on 3-inch bakelite tubing; 65 turns for 15, 25, and 50 meters, 180 turns for 100 meters, and 300 turns for 200 meters. The mica condensers C_1 had a capacity of $0.002 \mu f.$ and could stand 2500 volts. The variable air condensers C_2 had a capacity of $0.00045 \mu f.$ and were carefully calibrated. The inductance L was a coil of $3/16$ inch copper tubing 3.5 inches in diameter; 2 turns for 15 meters, 3 turns for 25 meters, 5 turns for 50 meters, 10 turns for 100 meters, and 30 turns for 200 meters. The electrodes surrounding the discharge tube were of sheet copper 2 cm wide. Copper ribbon $1/4$ inch wide was used for wiring the tank circuit and the tank current was measured by a 0-15 ampere radio frequency ammeter A (thermocouple type). The grid leak, $G.L.$, was a 40,000 ohm wire wound resistor to dissipate about 100 watts. The filament current was supplied by a 175 watt, 12 volt transformer T_2 , across whose secondary were the by-pass condensers C_3 ($0.002 \mu f.$).

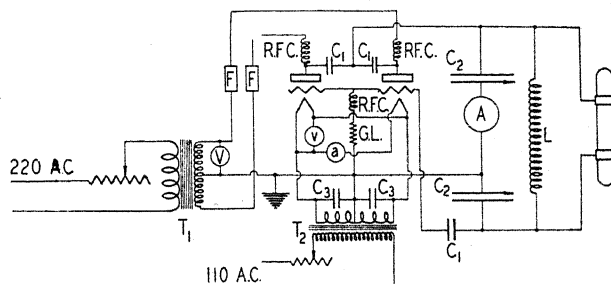

Fig. 1. Diagram of oscillatory circuit.

The discharge tube was of Pyrex glass, 30 cm long and 4.5 cm in diameter, with an optical glass window sealed into one end. Hydrogen was admitted to one end of the tube by means of a platinum tube and was pumped out at the other end, thus insuring a continuous flow of pure hydrogen. The platinum tube was 20 cm long, 1 mm in diameter with 0.1 mm walls. It was surrounded by a glass jacket through which commercial hydrogen was flowed. On heating the platinum tube to a dull red heat (about $600^\circ K$) by passing a current of about 16 amperes through it, an adequate flow of hydrogen was obtained through the discharge tube. The pressure could be varied either by changing the temperature of the platinum tube or by means of a valve which regulated the rate of pumping. Pressures were measured by a McLeod gauge.

PROCEDURE

The voltage between electrodes, which is equal to the voltage across the condensers C_2 was calculated from the formula $E = I/2\pi fC$ where E is the voltage across the condensers, I is the current through them in amperes, f is the frequency of oscillation and C is the capacity in farads of the two

condensers in series. The condensers C_2 were always adjusted so as to be of equal capacity. Hence, the ammeter A was at a potential node and its readings were independent of its capacity to earth.

A series of runs was taken at frequencies of oscillation corresponding to 15, 25, 50, 100, and 200 meters wave-length. The pressure was kept constant at 0.03 mm and the distance between electrodes was 5 cm. For each run, the tank current I , and consequently the voltage between electrodes E , was varied between the widest limits possible. The minimum voltage was

Fig. 2. Variation in the ratio of the densities of singlet and triplet lines with the electronic velocity (taken from Phys. Rev. 34, 437 (1929)).

approximately that at which the discharge first struck. The maximum voltage was determined by the output of the oscillator, that is, the voltage at which the plates of the valves became red hot.

Between these limits, photographs were taken of the discharge at regular intervals. The spectrograph used was a fairly fast two-prism glass instrument. Exposures were taken on Cramer Hi-Speed plates and were all of five minutes duration. Microphotometric traces were then made of all the spectra by means of a Moll self-registering microphotometer. From these traces, the density of the singlet line 4631.5 and the triplet line 4617.5 were

obtained by use of the relation: $\text{density} = \log d/d-h$, where d is the total galvanometer deflection in the absence of a line and h is the height of the peak on the trace corresponding to the line.

From the ratio of the densities of these two lines, the electron velocity could easily be determined since the variation in this ratio with electron velocity is already known³ (see Fig. 2). It might be remarked that although the curves of Fig. 2 were obtained using electrons of uniform velocity, they also can be used to find the *mean* electronic velocity; for the contribution to the ratio of the densities of 4631.5 to 4617.5 of those electrons whose velocity is greater than the mean will be balanced by the contribution of the elec-

Fig. 3. Variation in electron velocity with voltage between electrodes and frequency of oscillation.

trons whose velocity is less than the mean—provided always, that the mean velocity lies on the straight part of the curves.

RESULTS

Variation of electron velocity with voltage and frequency. The variation in electron velocity with voltage between electrodes and frequency of oscillation is shown in Fig. 3. At all wave-lengths, the electron velocity increases as the voltage between electrodes is increased. Moreover, for a given voltage between electrodes, the electron velocity, in general, increases with the wave-length of the oscillation. (The electron velocities at 15 meters seem to be an exception to this). The error in this method of finding electron velocities

is estimated at 2 volts while the experimental error is something under 0.5 volts. In other words, if two electron velocities were found to be 20 and 24 volts, they both might be in error by 2 volts, but their difference would not be in error by more than 0.5 volts.

Variation of electron velocity with gas pressure. To find the variation of electron velocity with gas pressure, a series of exposures were taken at various pressures between 0.01 mm and 0.06 mm. The wave-length of the oscillations was 25 meters, distance between electrodes 7 cm and voltage between electrodes 1020 volts. Since the ratio of the densities of the singlet and triplet lines varies with pressure as well as with electron velocity, it was necessary to correct the values of the ratio of 4631.5 to 4617.5 for the change in pressure. To the writer's knowledge, there has been only one attempt to find the effect of pressure on the excitation of the secondary spectrum. The results presented in that paper⁴ were of such a nature that the correcting factor could only be calculated roughly. Very approximately, then, it was found that the mean electron velocity decreased from 25 volts at 0.01 mm to 23 volts at 0.06 mm. pressure.

Variation of electron velocity with distance between electrodes. In general, a change in the distance between electrodes produced only a slight change in the electron velocity. At 15, 50, and 100 meters, increasing the distance between electrodes seemed to produce a slight increase in electron velocity, while at 25 and 200 meters, a slight decrease in electron velocity was found.

DISCUSSION

It is not difficult to understand why the mean electron velocity should increase when the voltage between electrodes is increased, and decrease when the pressure is increased; but at first one does not see why the electron velocity should increase when the wave-length of the oscillations is increased. To understand this, it will be necessary to consider more in detail the functioning of a high frequency discharge with external electrodes.

In a direct current Geissler tube discharge, with cold cathode, we know that the discharge is started by a few stray electrons in the gas which, under the action of the electric force between electrodes, produce more electrons by ionizing gas molecules. In this way, the number of electrons is increased to the point where the discharge strikes. Because of the unidirectional current, it is essential that there be a source of electrons, namely, the cathode. This source of electrons would not have been necessary, however, if the direction of the applied electric force were reversed before the electron cloud had time to disperse (by leakage along the walls of the tube, recombination with positive ions, etc.). This condition of affairs is obtained by applying high frequency electric forces to the discharge and since a source of electrons is no longer necessary we are able to use external electrodes.

Before a high frequency discharge will strike, however, a second condition must be fulfilled, namely, that the electrons shall attain ionizing velocity before they reach the end of the discharge tube. As a matter of fact, they

⁴ P. Lowe, Trans. Roy. Soc. Can. 20, 217 (1926).

probably must attain ionizing velocity before they have travelled the distance between the electrodes, since it is in this interval that they are under the influence of the electric forces. If, now we keep the voltage applied to the electrodes constant and increase the wave-length of the oscillations, it is evident that the time required for the electric force to reach its maximum value becomes longer and longer. Consequently, it will take the electron more time to reach ionizing velocity at the longer wave-lengths than it does at shorter wave-lengths. In other words, if an electron is to reach ionizing velocity in the same time at two different wave-lengths, the applied voltage must be increased for the longer wave-length, which means that the minimum striking potential will increase with the wave-length of the oscillation. This fact has been verified in the present experiments (see Fig. 3) as well as in those of others.¹

It has also been shown by others² that a discharge has its maximum conductivity under the same conditions that give the minimum striking potentials. Hence, by referring to Fig. 3, we must conclude that the conductivity of the discharge decreased with increasing wave-length. So if the discharge were operated at two different wave-lengths of oscillation, but with the same voltage applied to the electrodes, we would expect to find a smaller drop in potential along the positive column of the discharge which had the greatest conductivity. That is, for equal voltages applied to the electrodes, there will be a smaller drop in potential along the positive column of the discharge when it is operated at shorter wave-lengths. Consequently, at shorter wave-lengths, we would expect to find smaller electron velocities. This explains why, for a given voltage applied to the electrodes, the electron velocity increases with the wave-length of the oscillations.

The writer wishes to express his appreciation to the Grigsby-Grunow Company of Chicago, Illinois, which has supported this investigation. He is also indebted to several members of the Department of Physics for their interest in this work and especially to Mr. J. S. Owens, who assisted in the experimental work.

SECONDARY ELECTRONS OF HIGH VELOCITY FROM
METALS BOMBARDED WITH CATHODE RAYSBY PAUL BERTHOLD WAGNER
STANFORD UNIVERSITY

(Received November 20, 1929)

ABSTRACT

The magnetic spectra of high-speed secondary electrons emitted by Au, Ag, and Al, when bombarded with cathode rays of from 16 to 40 kv., have been photographed and densitometered. Beginning at the high-velocity end, the density is zero down to energy eV_0 , equal to that of a primary ray, then rises rapidly to a maximum at about $0.94eV_0$ for Au or Ag, or $0.85eV_0$ for Al, and then declines. The density is everywhere continuous. Its first derivative may be discontinuous at eV_0 , but nowhere else.

Thin targets show spectra sufficiently like those of thick targets to indicate that most of the secondary electrons come from very near the surface: for Au, within 0.2 micron even up to 40 kv; for Ag, over 0.2 micron only above 20 kv; for Al, over 0.5 micron only above 20 kv.

OBITUARY NOTICE

It is with great regret that we must record the death of the brilliant and promising young scientist whose work is described here. With his great enthusiasm for research, his conscientious thoroughness both instinctive and cultivated by his early education in Germany, and his unusually likable personality, he had every prospect of success and enjoyment in scientific research, and his death was a great loss, both to science and to his friends.

This paper is taken from his thesis for the degree of Master of Arts. As his death occurred in the sinking of the *San Juan*, on his way home to Los Angeles, just after handing in the thesis, he never had an opportunity to condense it for publication. This duty was therefore performed by the instructor, D. L. Webster, with whom he had done the research, but from whom only very little help was ever needed by such an original and able man as Paul Wagner.

I. INTRODUCTION

LITTLE work has been done on secondary electron emission at voltages ranging from 16 to 40 kv. At lower velocities, 10–12,000 volts, investigation has been carried on by Becker¹ (10–1,000 volts) and by Stehberger² (1,000–12,000). Both used the opposing field method. Plotting against the opposing voltage the number of secondary electrons having energy enough to overcome it, Becker obtained, for lower primary velocities, curves of the following general characteristics: for opposing voltages from zero to about 36 volts there is a rapid falling off in intensity; as the opposing voltage reaches higher values the intensity decreases gradually and uniformly, and at an opposing voltage equal to the primary voltage it suddenly drops to zero. This led Becker to distinguish between three types of electrons involved in the process of secondary emission; these he called "secondary" electrons,

¹ A. Becker, Ann. d. Physik 78, 228 (1925).

² K. H. Stehberger, Ann. d. Physik 86, 825 (1928).

"rediffused" electrons and "reflected" electrons. This classification was accepted by Stehberger. The distinction between secondary and rediffused electrons was based by Becker on the fact that his curves are straight from about 36 volts onward to primary voltages. Denoting by $N(V)dV$ the number of electrons having energies between V and $V+dV$, Becker's curves imply that $N(V)$ is constant except below 36 volts. This constant value gives the number of the electrons Becker calls rediffused; the excess over this, at voltages less than 36 volts, is composed of what he calls secondary electrons. The reflected electrons, finally, are those which have practically the primary energy.

Becker and Stehberger found that the upper limit of energy at which there is an appreciable number of what they call secondary electrons is 36 volts, whatever the nature or thickness of the target and whatever the primary voltage (within the range stated above). They concluded that these secondary electrons are electrons of the target material knocked out by primary and rediffused electrons, that rediffused electrons are primary electrons which have suffered a large number of small encounters with an atomic nucleus. Becker finds that for higher primary velocities the number of reflected electrons diminishes. Stehberger, being unable to apply opposing fields up to the higher primary velocities, made the assumption that reflection completely ceases for these higher primary velocities, basing his assumption on Becker's results for lower velocities.

There is arbitrariness in Becker's distinction between secondary and rediffused electrons, for we are not at all assured that the number of rediffused electrons does remain constant within the interval from zero to 36 volts. In this paper, therefore, the term "secondary" will be used from now on in a broader sense, denoting all the electrons coming from a target bombarded by primary electrons.

M. Baltruschat and H. Starke³ find that for voltages larger than 6,000 volts the number of fast electrons increases, and that at 30,000 volts even 80 percent of them possess velocities of the order of magnitude of the primary velocities.

Chilinsky⁴ did some work on the magnetic velocity spectra of secondary electrons produced from silver by primary electrons of 5 to 20 kv, and found that most of outgoing electrons had velocities about 0.8 of the primary value, and that the intensity in the spectrum fell off sharply at about 0.9 of the primary velocity.

Egon Lorenz⁵ carried on investigations, on the x-rays from the back of a tungsten target. He covered a wide range of voltages, up to 83 kv, and compared the spectrum of this so-called "stem-radiation" with that of the focal-spot radiation. The spectra are similar, but the entire stem-radiation spectrum is displaced, towards longer wave-lengths. Thus it approaches the axis at a point which is displaced from the short-wave limit of the focal spot.

³ Baltruschat and H. Starke, *Phys. Zeits.* **23**, 403, (1922).

⁴ S. Chilinsky, *Phys. Rev.* **28**, 429 (1928).

⁵ Egon Lorenz, *Zeits. f. Phys.* **51**, 71 (1928).

Beyond this point, it is true, there is a weak intensity extending as far as the focal spot limit, but Lorenz attributes this small amount of radiation to general scattered rays. He then interprets the apparent short-wave limit of the stem radiation by the hypothesis that the primary electrons eject electrons from the L (or other) levels of the target atoms, and that these secondary electrons cause the stem radiation; the short-wave limit of the focal-spot and stem spectra would then differ by just the frequency corresponding to the amount of energy required to extract these electrons. For instance Lorenz observes that at 22.4 kv primary voltage this difference in energy or voltage corresponds to the M level; and at 83.3 kv, to the L level. He states that this can be explained by the known fact "that the greater the energy of rays, the larger is the proportion of them absorbed in higher levels of any series in comparison with that in the other levels." Lorenz concludes that, if the primary cathode-ray energy is about 40 times that of, say, the M level, absorption would cease in that level and proceed to the next higher that is, the L level.

If Lorenz's explanation of his data is correct, it demands revision of current ideas on some other points. Each L electron ejected as a secondary electron must leave an L vacancy in an atom at the focus, and the filling of this vacancy will often, if not usually, cause the emission of a quantum of x-rays of one of the L lines. At 83 kv, an L quantum from tungsten carries off only about a tenth of the energy brought into the focus by the primary cathode ray, and the percentage of L vacancies causing L quantum emission may not be over 50 percent. Even so, however, if the number of secondary electrons is 20 or 30 percent of the number of cathode rays, and if they are chiefly from the L levels, we should expect 1 or 2 percent of the cathode ray energy to reappear as L -series radiation from the focus, as a result of the ejection of only such L electrons as escaped from the target, and much more as a result of the ejection of other L electrons not so directed as to leave the target. This is a considerably greater amount of energy than the total radiation from tungsten at 83 kv (about 0.75 percent). Thus this comparison, and also comparison with other data on line-emission efficiencies,⁶ lead to serious doubt about the hypothesis that many of the high-speed secondary electrons are ejected L electrons.

However, some of the secondary electrons must be of this type, and a further test is needed. For this purpose, the magnetic velocity spectrum suggests itself, and the next question is what to look for in it.

The secondary-electron velocity suggested by Lorenz's stem-radiation spectra, at least as a maximum, is that which would occur if all the kinetic energy possessed by a cathode ray as it enters the target is transferred to an L electron, which then loses only enough energy to escape from the atom. Most ejected L electrons, however, should have less kinetic energy than this maximum, for two reasons. First, most of the atoms from which the L electrons are ejected are not at the surface of the target, and there are energy

⁶ D. L. Webster, Proc. Nat. Acad. of Sci. 14, 330 (1928). Data here indicate that when an 80 kv. electron strikes a block of silver, it has a line-emission efficiency of only about 0.1 percent.

losses along the paths of both the primary and secondary electrons. And second, in the act of ejection, the cathode ray should probably not transfer all its energy to the L electrons. It may be possible to eliminate the former of these causes for deficiency of energy, if the target can be made thin enough, but the latter is inherent in the atomic process. Thus even with an infinitely thin target, the energy limit described above might at best be looked for in the velocity spectrum only as a discontinuity in the first derivative of the intensity; and with a thick target, only in the second derivative.

These predictions are somewhat discouraging, but not completely so. For even if the secondary electrons were of uniform velocity, like the primary, the discontinuity in the x-ray spectrum of the stem-radiation would still be only in its first derivative. And uniform velocity means, for the velocity spectrum, not simply a finite discontinuity in some derivative, nor even in the intensity function itself, but in its first integral. In general, the order of the lowest derivative in the stem-radiation spectrum, having a finite discontinuity, should be two units higher than that in the velocity spectrum. Thus the better of the two spectra, as evidence on the question in hand, should be the velocity spectrum, which ought therefore to be explored thoroughly. And regardless of all such hypotheses as are discussed above, such exploration will surely improve our understanding of the process of secondary electron emission.

II. APPARATUS AND METHODS

The apparatus used here was of the well-known type for semicircular focussing of a magnetic spectrum, as described by Robinson,⁷ and is illustrated in Figures 1 and 2. The source of the secondary electrons to be

Fig. 1

analyzed into a spectrum is the target, T , shown from two directions in Figs. 1 and 2. The familiar magnetic focussing of the electrons is illustrated in Fig. 2, while Fig. 1 shows how the primary rays came along the lines of the magnetic field, as in Chilinsky's apparatus. Thus they travelled in straight

⁷ H. Robinson, Proc. Royal Soc. A104, 455 (1923).

lines, from the Coolidge cathode in the glass bulb at the left, to the target *T*. The current producing this field ran in a pair of Helmholtz coils, indicated in Fig. 1 by the broken segments marked *H*. The brass box, in which the electrons made their semicircular paths, communicated with the glass bulb only through the very narrow slit *S*, and both of the chambers needed very good vacuum. Therefore, even though a test showed that the pump leading from the box alone would evacuate the bulb satisfactorily, a pump from the bulb was added as a precaution.

The target was sometimes a solid rod of aluminum as shown here, sometimes a brass rod with copper, silver, or gold soldered to it, and sometimes a brass tube, 7 cm deep, with a bore of 1 cm diameter, covered at the end with aluminum, silver, or gold leaf, to make a thin target. In each case, the primary rays struck the target at 45° , and the secondary rays used left it at the same angle, being thus 90° from the primary. The thicknesses of the thin targets were: Al 0.53×10^{-4} cm, Ag 0.18×10^{-4} cm, Au 0.23×10^{-4} cm.

Fig. 2

Some other numerical data were as follows: slit *S*, 1.4 cm by 0.025 cm; diameter of hole through which the cathode rays approached the target, 0.2 cm; fraction of the cathode rays going through this hole, about 5 percent; radius of the Helmholtz coils, 17 cm; center of whole Helmholtz coil system, at the center of an electron path of radius 5 cm; non-uniformity of field (by test coil) not over 0.9 percent from its value at the center, anywhere on a radius of 6 cm.

The voltage applied to the primary cathode rays was obtained by connecting the cathode to the negative line of the D.C. system of the laboratory, and the brass box to the neutral line, which was grounded. It could be held constant to better than 0.3 percent, and the fluctuations due to the primary A.C. were far less than this.

For final use, spectra were photographed at four voltages, 16, 20, 30, and 40 kv, the first two with 1 ma (of which, as noted above, only about 5 percent reached the target), and the last two with 0.6 ma. To insure constancy of voltage and magnetic field in each exposure, the following procedure was adopted. First, the film was inserted, the box closed, and the ap-

paratus pumped to a high vacuum. Second, the current in the Helmholtz coils was set for a value such as to deflect secondary electrons of primary velocity into semicircles of 5 cm radius, and it was watched carefully thereafter. Then the high voltage was turned on, adjusted, and watched by another observer, usually Mr. B. G. Eaton, to whom hearty thanks is due for the care with which he rendered this assistance. Third, the filament was heated gradually, taking about half a minute to heat, so as to avoid voltage disturbances due to slight evolution of gas, and it was maintained at the right temperature for 5 minutes. Finally, the filament current was shut off, then the high voltage, and last the magnetizing current. Thus all the electrons had a primary voltage and deflecting field, each uniform to 0.3 percent, so that no discontinuity in the magnetic spectrum could be blurred by any lack of constancy involving energy changes as great as 1 percent.

Beyond tests for discontinuities, however, this work is purely qualitative although the conditions of exposure and development of the films were kept as constant as possible, to facilitate the comparisons of films. Especial care in this respect was applied to pairs of films, for thick and thin targets of the same metal at the same voltage, which were developed together.

Along with all the ordinary sources of photographic errors, it was unfortunately not found possible to eliminate entirely the effect of stray light from the filament. Tests without high voltage, however, (thus omitting the cathode rays) showed that the most serious fogging by such light occurred only in the low-velocity region. In the high-velocity region, say above half the primary ray energy, where most of the secondary electrons appeared, the fog was very light and practically constant. Thus, fortunately, it can be neglected in discontinuity tests or in qualitative comparisons confined to this high-velocity part of the spectrum.

III. RESULTS

Some densitometer graphs, comparing thick and thin targets of Al, Ag, and Au are shown in Figs. 3, 4, and 5 respectively; and some for thick targets only, of Al, Cu, and Au, in Fig. 6.

As will be seen on inspection of these graphs, *all these spectra are continuous.*

With regard to discontinuities in the derivatives of density or number of electrons with respect to velocity, it is evident that *there is apparently a real discontinuity in the first derivative, in every spectrum, at its high velocity end which is always found on measurement to occur at a velocity equal to that of the primary cathode rays. Aside from this point, however, no discontinuities have been found.*

First-derivative discontinuities would of course be much easier to detect than second, of the same relative proportions. Considering now only the thick targets, it has already been noted that we cannot expect to find any evidence of electrons ejected from the inner orbits, except in second-derivative discontinuities. Therefore, so far as we can tell here, such electrons may constitute several percent of the secondary electrons. But if they con-

stituted a majority, it would be a different matter. If, for example, in gold at 20 kv the majority of the secondary electrons were ejected from the M

Figs. 3, 4, 5 and 6

levels, we should expect to find relatively few electrons of energy greater than $(20-4)$ kv, or $0.8eV_0$, and just below this energy we should expect the density to begin to increase rapidly. The facts, however, are totally different

from any such prediction, not only in this spectrum, but in all the spectra. We must, therefore, conclude that, although some of the secondary electrons undoubtedly do arise from ejections from the inner orbits, they are a very small minority.

Turning now from discontinuity tests to qualitative information on other matters, still on thick targets, we find for all these elements, Al, Cu, Ag, and Au (as Chilinsky found for Ag up to 20 kv) that most of the high-speed secondary electrons have very high speeds. In terms of kinetic energy the maximum densities in these spectra occur at energy values bearing nearly constant ratios to the primary energy, eV_0 . For Al, this optimum energy eV_m is about $0.85 eV_0$; for Cu, about $0.90 eV_0$; for Ag and Au, each about $0.94 eV_0$. The probable errors in these ratios are several percent, of course, especially for Cu, for which relatively few photographs were made.

Below the optimum energy, in every case, the density declines rapidly, reaching half its maximum somewhere around 0.6 or $0.7 eV_0$. Part of this decline may result from a decline in the photographic effect per electron, though not if each electron causes development of one grain, as may be possible. These statements on densities give, of course, only a qualitative idea of the laws governing the number of electrons per unit energy interval, but this number must vary in a manner roughly similar to these densities.

Since the conclusions drawn here differ radically from those of Lorenz, a question arises, whether the difference is due to theoretical assumptions in the interpretation of the data, or to some hidden source of experimental error. From the present data on the velocity spectra of the secondary electrons, we may predict roughly the form of the x-ray spectrum of the stem radiation they might excite. Considering only gold, as the element most like Lorenz's tungsten, the outstanding feature is the concentration of the secondary electrons in the general region around $0.9 eV_0$, ± 0.1 . The x-rays due to such electrons would not be expected to show any very sharp short-wave limit, but the general form of their spectrum would be much like that of the x-rays from the focal spot, except that it would be shifted to wave-lengths about 10 percent longer, and blurred out by ± 10 percent, more or less. Considering the short-wave limit more carefully, what it should show, as noted above, is a finite discontinuity in a derivative of order two units higher than that of the discontinuous derivative in the velocity spectrum. Therefore, since the velocity spectrum has its discontinuity in its first derivative, the x-ray spectrum should start, as measured from its short-wave limit, more or less like the curve $y=x^3$. In other words, it should have a graph which runs very low near the limit, and curves upward rather sharply at a wave-length somewhat greater. It is, therefore, not inconceivable that this sharp upward curvature might occur in the region where most of the secondary electrons would have their individual short-wave limits, that is, around 10 percent above the true short-wave limit. This is just about the region where Lorenz found a strong upward curvature in each of his spectra, assuming it to be a short-wave limit and assuming the weak radiation of still shorter wave-lengths to be stray rays from the focal spot. Thus

it may well be that the only cause for difference between his conclusions and the present lies in these assumptions, and that the data are consistent within the limits of reasonable experimental errors.

Turning now to the thin-target velocity spectra, they prove somewhat disappointing. Differences from the corresponding thick-target spectra are found only in Al and Ag, and there only above 20 kv. However, some recent theoretical work by Bothe,⁸ on the stoppage of cathode rays in matter, throws light on this point. In thick targets, only very few cathode rays are stopped far short of their normal range, by large losses of energy; but practically all of them are deflected by nuclear attractions without much energy loss, in very short distances. Thus, at the speeds used here, they have completely lost all sense of direction before they have gone a micron. Qualitative calculations on rather loose assumptions related to those of Bothe, make it quite reasonable to expect many of the cathode rays deflected back out of the metal to have had very short paths within it. Such deflected cathode rays (or rediffused, as Becker would call them) should therefore have two characteristics in common with the secondary electrons observed here: first, that each electron should retain a large fraction of its initial kinetic energy; and second, that a metallic film, whose thickness is small compared to the range of a cathode ray in the metal, should nevertheless be thick enough to give practically the same velocity spectrum as a thick target. The agreement of theory and observation here tends to confirm the view that most of these high-speed secondary electrons are rediffused cathode rays.

With regard to how thin a target must be, to give "single scattering," and really give the velocity spectrum of an infinitely thin target, it seems probable that this requirement of thinness is considerably more severe than that for obtaining a "thin-target" x-ray spectrum. For velocity spectrum work, these spectra show that 0.2 micron gold is "thick" even at 40 kv; likewise 0.2 micron silver and 0.5 micron aluminum are each thick at 20 kv. To consider such films really "thin" from this viewpoint, these voltages must be greatly exceeded.

⁸ W. Bothe, *Zeits. f. Physik* 54, 161 (1929). Mr. Wagner had not seen Bothe's work, but this application of Bothe's theory tends to confirm the views Mr. Wagner expressed, as to the origin of the secondary electrons, and is therefore a reasonable extension of his paper.

ELECTRODYNAMIC DAMPING IN PULSATING STARS

BY ROSS GUNN

NAVAL RESEARCH LABORATORY, WASHINGTON, D. C.

(Received November 29, 1929)

ABSTRACT

Small radial pulsations of stars are shown to be highly damped by electrodynamic forces when the star has a magnetic field unless the star is very diffuse. The author's theory of the permanent magnetic field of the sun indicates that the field is produced by regenerative means which is initiated by a small field arising from some more fundamental mechanism. The small initial field is probably produced by the rotation of the star combined with a separation of charge, although it may conceivably arise in other ways. Thus rotating stars will have a magnetic field and cannot pulsate, and conversely stars which pulsate can have no magnetic field and probably do not rotate. This is in accord with the idea that Cepheid variables, being youthful giants, are so large that they would be unstable under rotation. These considerations appear to remove the difficulties encountered by Eddington in his detailed theory of star pulsations.

A CLASS of stars known as Cepheid variables are observed to go through regular periodic changes in their brightness, color and spectrum. It appears that the variation must be due to a variation of surface temperature rather than to eclipses or a rotation of the star, for observation shows that the rise in surface temperature is much more rapid than its decline. The astronomical observations are well explained by the pulsation theory which was first proposed by Shapley and later worked out in detail by Eddington.¹ This theory attributes the observations to a periodic radial expansion and contraction of the star under the joint action of gravitation, radiation and gaseous pressure. In this theory it is supposed that a star is in internal equilibrium and that the pressure at any level due to the weight above it is just balanced by the outward gaseous and radiation pressure. Let the entire star be uniformly compressed. On removing the constraint the internal radiation and gaseous pressures will expand the star and the inertia of the moving material will cause it to expand beyond its equilibrium position. This may give rise to an oscillation which can be sustained if energy is supplied in phase with the variation and if it is of sufficient magnitude to overcome the dissipative forces. Eddington has examined the problem and finds that if the pulsation of Cepheid variables is to be explained satisfactorily nearly all stars should pulsate and the phenomena should be more generally observed than is actually the case. In the treatment of the subject of star oscillations no account has been taken of electrodynamic forces and as we shall see presently these forces may be large and always act in such a manner that they tend to damp out very rapidly any radial oscillation of a star.

¹ Eddington, *Internal Constitution of the Stars*, Cambridge Press (1926).

Indeed, the present paper shows that radial oscillations of a star can exist only under very special conditions; conditions which appear to be satisfied in the youthful giant stars.

In an earlier paper² the writer outlined a theory of the origin of the magnetic fields of the sun and earth. The theory showed that any highly ionized star having radial temperature or gravitational symmetry would be expected to build up a large magnetic field by regeneration if a small initial magnetic field were present to start the regenerative process. All stars possess the requisite radial temperature and gravitational symmetry and it is only necessary to produce a small initial field to bring about their complete magnetization. The small initial field might be attributed to a "magnetic collision" with the stray magnetic field of another star or in some other way. Earlier work on the sun³ indicates, however, that a star's magnetic field is more or less confined by the diamagnetic action of the ions in the stars atmosphere which execute long free paths. It seems more reasonable to consider the initial field as arising from gyromagnetic effects or from the gross rotation of the star combined with a slight gravitational or thermal separation of charge. Such an assumption leads to the correct sign for the magnetic field of the sun and earth. The general conclusion is that any star which possesses appreciable angular momentum will be magnetized. We must therefore examine what effect a magnetic field may have on the stability of a star and in particular we shall examine the effects produced by the magnetic field when the star is subject to a small symmetrical radial oscillation.

Assume for simplicity that the magnetic field inside a star is uniform and consider the forces acting on a ring of star material which lies in a plane perpendicular to the magnetic field and which expands and contracts radially with the star itself. In order to keep the essential physics before us let us also assume that the ring has a mean equilibrium radius R_0 and that any expansion or contraction of the ring will set up elastic restoring forces which are proportional to the displacement of the ring from the equilibrium position. On account of the symmetry we may describe the process by writing down the equations of motion for the material enclosed by unit volume of the ring. In addition to the inertial and elastic forces, account must be taken of the dissipative forces and in the following we shall consider only those of electromagnetic origin. Consider an expanding ring of star material. As the ring expands the magnetic flux enclosed by the ring is increased and an electromotive force is induced. This electromotive force produces a current in the closed circuit of the ring which is always in such a direction as to oppose the motion. Suppose the ring is expanding outward with a velocity V . Then the electric field E produced by the motion is

$$E = V \times B \quad (1)$$

where B is the constant impressed magnetic field intensity of the star. The force F acting on unit volume of material is by aid of (1)

² Gunn, Phys. Rev. 34, 335 (1929).

³ Gunn, Phys. Rev. 33, 614 (1929).

$$\mathbf{F} = \mathbf{i} \times \mathbf{B} = \sigma(\mathbf{V} \times \mathbf{B}) \times \mathbf{B} \quad (2)$$

where \mathbf{i} is the current density and σ is the conductivity. For the purposes of the rough calculations in this paper the classical expression for conductivity can be used and Eq. (2) reduces (in the special case where the ring expands in a plane perpendicular to the impressed magnetic field) to

$$\mathbf{F} = -\sigma B^2 \mathbf{V} = -\frac{N e^2 \lambda B^2}{2(3mkT)^{1/2}} \mathbf{V} \quad (3)$$

where N is the number of ions per cm^3 , e the ionic charge (e.m.u.), λ the mean free ion path, m the mass, k the Boltzmann constant and T the absolute temperature. It has been shown previously⁴ that the expression for the electrical conductivity given by Eq. (3) breaks down and the conductivity decreases greatly when the mean free path of the ion approaches (in numerical value) the radius of the circle generated by the ion as it spirals about the impressed magnetic field. It has also been shown³ that in the outer surface layers of the sun the mean free paths of the ions are longer than this critical radius and the conductivity of the region low. Thus the currents flowing in a very diffuse star or in the outermost layers of the star are small and the resulting damping is probably unimportant.

If we measure r from the equilibrium position of the ring, the equation of motion for a typical volume element is

$$\rho \frac{d^2 r}{dt^2} + \sigma B^2 \frac{dr}{dt} + K^2 r = 0 \quad (4)$$

where ρ is the density of the star material and K^2 is a constant which must be determined by a complete analysis or by observation of the free period of oscillation. With $2u = (B^2 \sigma / \rho)$ and $v^2 = K^2 / \rho$ the solution of (4) is of the form

$$r = C_1 e^{[-u + (u^2 - v^2)^{1/2}]t} + C_2 e^{[-u - (u^2 - v^2)^{1/2}]t} \quad (5)$$

and may represent a completely damped pulse, a critically damped oscillation or a free oscillation depending on the value of the coefficients. From Eq. (5) it is seen that any mean displacement will be reduced to roughly one e^{th} its initial value in a time

$$t = \frac{1}{u} = \frac{2\rho}{B^2 \sigma} \quad (6)$$

and if the system is oscillatory it will oscillate with a frequency

$$f = \frac{1}{2\pi} \left(\frac{K^2}{\rho} - \frac{B^4 \sigma^2}{4\rho^2} \right)^{1/2} \quad (7)$$

It will be noted in passing that the frequency of oscillation is sensitive to changes in the value of B , for σ will have fairly large values in any ordinary

⁴ Gunn, Phys. Rev. 32, 133 (1928).

star. It must be remembered that Eq. (6) only applies to rings which expand at right angles to the magnetic field. In all other orientations the damping will be somewhat less and there is a tendency for the star to expand more at the magnetic poles than at the equator. In fact, closed circuits in a plane containing the magnetic axis might be expected to produce no damping of the type we have considered. Moreover, certain types of oscillation can be conceived wherein any typical current ring suffers no change in area but takes on successive elliptical forms. Such an oscillation would induce no current and electrodynamic forces would not be important.

It will be necessary to consider an actual case to determine the importance of electrodynamic forces. The only star which we definitely know possesses a magnetic field is the sun and earlier work,^{2,3} has indicated that its internal magnetic field intensity was not less than 10^4 gauss. We shall apply a disturbing force to the sun in such a manner as to set it in radial oscillation and calculate by Eq. (6) and (3) the time it will take the oscillation to die out. We will take representative values of the quantities as follows:

$$\begin{array}{lll} B = 10^4 \text{ gauss} & \rho = 1.4 \text{ gm/cm}^3 & N = 10^{23} \text{ ions/cm}^3 \\ e = 1.59 \times 10^{-20} \text{ e.m.u.} & \lambda = 10^{-6} \text{ cm} & \\ m = 10^{-27} \text{ gms} & k = 1.37 \times 10^{-16} & T = 10^7 \text{ degrees} \end{array}$$

which leads to a value of $\sigma = 6.25 \times 10^{-6}$ e.m.u. Thus by Eq. (6) the time for the mean solar displacement to be reduced to $1 e^{th}$ of its initial value is 4.5×10^{-3} seconds. It is therefore clear that no oscillation can take place and the sun is in stable equilibrium. It must be emphasized that this conclusion is only true for small oscillations which produce no appreciable change in the impressed magnetic field. When the oscillations are large the problem offers mathematical difficulty but qualitatively it appears that large oscillations would be damped out much less rapidly than small ones and that the surface layers will reach equilibrium well before the deeper ones. If it is assumed that the numerical values which have been chosen in the case of the sun are representative of stars in general, it is doubtful if any star having a magnetic field can oscillate over any extended period of time. We must therefore interpret the occurrence of true pulsating stars to mean that the star does not have a magnetic field or that it is so diffuse that the ion free path is long and the magnetic field reduces the electrical conductivity almost to zero.

The writer's theory of the origin of the permanent magnetic fields of the sun and earth is based on a regenerative action which requires a small initial magnetic field to trigger it off. The small initial field is most simply accounted for by a rotation of the star and it seems correct to assume that every rotating star is highly magnetized. Conversely, a star which has no magnetic field would not be expected to rotate. The foregoing considerations definitely suggest that a true pulsating star does not rotate. Appeal to observation shows that all the stars that are suspected of being true

pulsating bodies are youthful giants which astronomers believe would break up if they were possessed of any great amount of angular momentum. This observed fact seems to bear out the conclusion that true radial pulsation of a star is possible and the argument shows that the existence of such entities in the universe does not necessarily mean that all stars should be unstable and exhibit a radial pulsation.

Jeans⁵ has concluded that the pulsation theory is inadequate to explain the observations and chooses to think of the variables as stars in the process of breaking up to form binary systems. Consideration of electrodynamic damping might be favorable to this theory if it can be shown that the probability of rotation for a star is very much greater than the observed probability for the occurrence of a nonpulsating star. Unless some such statistical relation be established the considerations of this paper appear to support the ideas of Shapley and Eddington as formulated in their pulsation theory. While it is too early to decide whether the present considerations support or disprove the pulsation theory of Cepheid variables, it appears that electrodynamic forces play an important part in stabilizing a star and they must be considered in any complete study of its history. The possibility that electrodynamic loading of the type we have considered may account for certain observed features of Novae is now being investigated.

Effect of Red Light on Stopping Potentials of Photoelectrons Liberated by Blue Light

In "Naturwissenschaften" (41, 806-807, October 11, 1929) was published a note by Erich Marx, announcing observations which seemed to show that red light superimposed on blue light falling on a photoelectrically sensitive potassium surface had the effect of decreasing the maximum kinetic energy of emission of the electrons liberated by the shortest wave blue light. This is a most surprising and important result, if true. Details of the experiment were missing, but the only care necessary to observe this effect seemed to be that of preventing light from striking the anode directly or indirectly while determining the stopping potentials of the photoelectrons. In fact, Marx explained that the phenomenon was easily observed qualitatively, on any commercial potassium cell.

Now, since most commercial model photoelectric cells are of the central anode type and require upwards of a hundred volts, at least, to produce saturation of the photoelectric current, shifts ranging from a fraction of a volt to a few volts in the voltage-current relation can only be detected at a voltage where the current approaches zero. Hence, it is undoubtedly at the foot of the stopping potential curves that Marx claims to have observed the effect of the red light superimposed on the blue. But, as rather carefully pointed out by Millikan [Phys. Rev. 7, 18, 355 (1916)] and quite generally proven by experimental results, this part of the curve for a given anode is not a function of the cathode at all and can only be affected by a change in light frequency. Certainly there exists no sound reason for only the highest frequency of the incident light being altered, so the so-called "new photoelectric phenomenon" of Marx is hard to reconcile with experience or theory.

Such an apparent reduction of the retarding

potential as cited above, however, would be produced if some of the incident or reflected light fell on an anode sensitive more to red light than to blue, and it seems highly probable that such was the case. For, in the first place, Marx stressed the importance of preventing light from falling on the anode, a precaution unnecessary if the anode were not light sensitive and one practically impossible to put into effect. In the second place, it is a matter of common observation that the anodes of potassium photoelectric cells frequently respond better to red light than the cathodes, a fact which suggested to Campbell [Phil. Mag. 6, 633 (1928)] a method of making red-sensitive potassium cathodes. Undoubtedly the sensitivity of the anode to red is due to a thin film of potassium spontaneously deposited thereon, and these films naturally respond to light of longer wave-length than the bulk metal or heavy layer of the cathode [Ives and Olpin, Phys. Rev. 34, 117 (1929)]. Whenever potentials are applied to retard electrons released at the cathode they accelerate at the same time any electrons liberated from the anode, and the measured current will be the difference between the number of electrons reaching and leaving the cathode. Since potassium, in bulk form or thick layers, responds well to blue light but not to red light, whereas potassium in the form of thin films on metals, responds well to red light, it is at once evident that if any scattered light fell on the anode, the presence of red light will occasion a greater reverse current and consequently the voltage at which the current becomes zero will be less than for blue light alone.

In order, therefore, to make a complete check of the "Marx phenomenon," a cell having an anode absolutely insensitive to

light should be used. I had available such a cell, made by preparing the cathode in a separate chamber and then slipping it into place within a nickel anode coated with soot. The cathode was not coated with potassium but with sodium, sensitized by the introduction of small amounts of sulphur and oxygen until the response to red light was far greater than that of potassium-hydride cells [Olpin, Abs. 57, Bull. Am. Phys. Soc. vol. 4, No. 2

a tungsten filament, and the red light similarly produced by using a No. 29-Ek Wratten filter. The photoelectric currents were read on a high sensitivity Leeds and Northrup galvanometer.

The results of this test are shown in Fig. 1. There was absolutely no effect of the red light on the electrons emitted with maximum kinetic energy, but an increase in the number of slower electrons. The voltage-current curve

Fig. 1.

(April 6, 1929) Phys. Rev. 33, 1081 (1929)]. These alterations from the Marx experiment may be criticized, but there seems to be no reason for expecting potassium to behave differently from sodium in the property under discussion, unless it be the fact that potassium is far more likely to pass by vaporization to the anode than is sodium. The blue light was produced by inserting No. 49-EK Wratten filter in the path of radiations from

for both red and blue light falling simultaneously on the surface was exactly the sum of the voltage-current curves for the two colors of light used separately. This was found to be equally true when yellow light was used in place of the red.

The Origin of Snowflakes

Experiments begun in 1920 on the conditions governing the origin and growth of snowflakes have now met with some success. It has been found possible to produce an opalescent cloud of snowflakes, to put individual particles of this cloud under microscopic observation within about five seconds of their inception, and to control their growth

up to a diameter about four times that at which their outlines become distinguishable.

The experimental method consists in passing a current of cold dry gas—obtained by the evaporation of liquid oxygen or liquid air—into a mixing tee where it may meet a current of air and saturated water vapor supplied at a temperature a few degrees above 0°C .

The mixture passes immediately into the top of a vertical observing chamber kept at a few degrees below zero, thence down through the chamber and out by horizontal lateral passages. The bottom of the chamber is made of a glass plate with a fine scale engraved or etched on its upper surface. A microscope objective under the plate is placed so as to form a magnified image of the scale and of any deposit that may occur on it, in the focal plane of an eyepiece or on a photographic film. Illumination is downward through the observing chamber. With these arrangements, the admission of the moist air to the mixing tee is accompanied by a reddening and darkening of the field of view, and in a few seconds the glass receives a deposit of particles of the order of 5×10^{-4} cm in diameter—too small to permit observations on their shape with the optical system used. An additional supply of vapor to the chamber results in the visible and rapid growth of these particles to sizes which display definite outlines. Diameters of 2×10^{-3} cm are frequent. The particles thus grown may be held under observation for a minute or more, and photographed.

After the process of growth has started, it is not possible to bring onto the plate an additional deposit of particles of the original size. The opalescence occurs as usual, but produces only a further growth of the particles already on the plate. This indicates that snowflakes, like raindrops, grow at the expense of their smaller neighbors, and implies that the equi-

librium vapor pressure above a particle of ice decreases with increasing dimensions. The opposite effect has been observed by Farnsworth [Phys. Rev. **34**, 684 (1929)] in the case of small copper crystals growing at the expense of a large one.

The crystalline character of the deposit is obvious from an inspection of the photographs. Many of the particles show twinning, and a few appear to be aggregates. More common than either of these are forms without internal markings, perfectly transparent, revealing in their outlines the symmetry characteristic of the hexagonal system. The symmetry is not merely that of external form, for when these crystals are made to grow, each of the six faces advances at the same rate, so that the outline remains similar to itself. This observation indicates that the faces are alike in physical properties, and that therefore the particles are monocrystalline. The deposits also contain abundant material for the study of the so-called cubic crystals which have been reported occasionally by observers of naturally formed ice crystals.

The method is probably applicable to the formation and growth of small single crystals of substances other than water, and affords a means of studying problems of crystal structure in the light of the kinetic theory.

Inhomogeneities in Crystals

Ever since Griffiths proposed the existence of internal flaws in apparently perfect crystals as an explanation of certain anomalies in their behavior, various workers have attempted experimental verifications of this hypothesis. There have likewise been attempts to justify it on theoretical grounds and thus bring it within the domain of regular and predictable phenomena.

The subject derives its importance from its bearing on the validity of some highly fundamental physical measurements. Among these are the refined determinations of compressibility such as those of Bridgeman and the determinations of x-ray wave-lengths based on the assumption that the calcite crystal is perfect and homogeneous. Other determinations affected are those of all elastic

constants, thermal and electrical conductivities and densities. All the data of crystal energetics are subject to large and unpredictable errors if internal inhomogeneities exist.

Mehl and Canfield in a note (Nature, Sept. 28, 1929) have discussed the question of voids in crystals and conclude that the experimental evidence, particularly the recent measurements of x-ray wave-lengths with a ruled grating (Beardon, Proc. Nat. Acad. **15**, 6 (1929)) cannot be reconciled with their existence.

The most important recent paper supporting the inhomogeneity hypothesis is by Zwicky (Proc. Nat. Acad. **15**, 11 (1929)) who contends not for the presence of voids but for planes of altered density occurring at fairly regular intervals within the lattice and di-

viding it into a sort of mozaic. He has previously secured experimental evidence of such structure on the *surface* of etched metal crystals. The paper here referred to is devoted to a theoretical treatment of the subject, resulting in a prediction of the required phenomenon, and it is this to which the present writer wishes to take exception.

In setting out on his discussion the author makes (in substance) the following steps of reasoning:

Crystals in general contract laterally when they are elongated in one direction. Hence, if we picture the crystal as built up of planes of atoms, the withdrawal of neighbor planes permits the atoms of a given plane to come closer together. Hence the atoms of any one plane would draw nearer together if that plane were isolated and allowed to come to its equilibrium configuration.

This reasoning is fallacious. The elongated crystal is not in equilibrium, but has had work done on it by external forces; the configuration it assumes is determined by the condition that the work done by the external forces shall be a minimum. As a matter of fact the process of withdrawing the neighbor planes *pulls* the atoms of the given plane into closer proximity. A plane of atoms when isolated might expand or contract from its

dimensions in the lattice, depending on the density of packing of the atoms in the plane. For example a (111) plane of a homo-polar face-centered cubic lattice would expand; a (100) plane would contract. Since the remainder of the proof rests on the argument already outlined it requires no comment. Although the reasoning is called thermodynamic, it is in reality dynamic, with the words "free energy" substituted for "potential energy."

As regards the experimental evidence, there can be little doubt that an actual mozaic structure does exist on the *surface* of a crystal. In fact the effect is to be expected as a result of the surface energy, as the present writer hopes to show in a paper now in preparation. But it must be emphasized that the experimental evidence now at hand establishes the existence of *surface inhomogeneities only*. The non-agreement of predicted tensile strengths with experimental values—the main prop of the mozaic argument—is susceptible of too many other explanations to serve as *prima facie* evidence of internal inhomogeneities.

A New Relativity Theory of the Unified Physical Field

I have succeeded in applying to the above question what appears to be an important new conception regarding the significance of relativity mathematics with noteworthy results. I have abandoned altogether the quasi-geometrical interpretation with such hazy notions as parallel displacement in a curved space of n dimensions. Instead, we construct an indeterminate vector field by means of Eddington's displacement rule (considered now as an association rule), and identify it at every point with the velocity a material particle might have if present there and then. Vector lines in this field are necessarily the orbits of material particles under any physical conditions.

We now construct an indeterminate tensor field, and by its means define the invariant magnitude of the elementary arc of these vector lines. Actual physical vector and tensor fields are necessarily determinate at every point, and these are defined as usual by applying the association rule round a closed

loop. This gives the usual symmetric and antisymmetric field tensors.

When the antisymmetric field tensor vanishes the vector lines reduce to Einstein's so-called geodesics. The electric field is given by the antisymmetrical tensor, and here the vector lines become mathematically equivalent to the known orbit equations. Maxwell's first set of field laws are identically satisfied, and the set referring to electric charge and current are approximately true for small fields. In strong fields in the neighborhood of atomic nuclei the electron orbits reduce again to geodesics, independent of negligible radiation due to their acceleration, and Maxwell's second set of laws no longer holds. This is obviously very strong support for our theory. But further; the introduction of field laws which reduce to Einstein's in the pure gravitation field appear to lead to a principle of selection among the orbits in nuclear regions.

Before leaving England this summer, the

writer prepared a hurried account of the above theory intended for publication in the Proceedings of the Royal Society. It unfortunately gave no explanation of the mathematics which latter were faulty at one point. A careful and complete revision has now

proved the soundness of the theory, and publication will follow as quickly as possible.

The Microstructure of Some Magnetic Alloys of High Platinum Concentration

In a recent paper [Phys. Rev. **34**, 1217 (1929)] the writer has described an attempt to measure the magnetic properties of ferromagnetic atoms in a somewhat isolated state. The method used was to study alloys of platinum with a small percentage of cobalt. Alloys of 5% cobalt and 10% cobalt were both ferromagnetic. Provided these alloys are solid solutions, which was believed to be the case, the cobalt atoms in them could be regarded as mostly isolated from one another by the intervening platinum atoms.

A microscopic study of these alloys has since been made. The diagram of thermal equilibrium has not been obtained for the Pt-Co series, although Carter has investigated many high-platinum alloys and believes platinum and cobalt form an isomorphous series of solid solutions. However, it was necessary to be sure that two solid solutions did not exist together in a given alloy, with the result that a particular cobalt alloy would generally consist of a cobalt-rich phase plus a platinum-rich phase, or of a platinum-cobalt mixed crystal in pure platinum; in this case, increased platinum concentration would not mean further isolation of cobalt atoms, but a different proportion of the two phases.

Sections of each alloy were prepared, polished and etched with hot aqua regia. Wires in the hard-drawn state showed, under the microscope, that their crystals were elongated and distorted in the direction of strain. In the annealed state, however, each alloy showed the polygonal polycrystal pattern characteristic of pure metals or single solid solutions. If two phases were present in, say, the 10% cobalt-90% platinum alloy, they would have to exist in nearly equal proportions or one phase might be present in a

small quantity between the grain boundaries. The 5% cobalt alloy, however, showed the same structure, although it, too, could not contain equal amounts of the two phases. In neither alloy was the characteristic eutectic structure of one phase imbedded in the other present. The sections were etched a little at a time and examined at each stage, but intercrystalline material was never detected. The sections etched uniformly, but the 5% cobalt several times more slowly than the 10% cobalt; as the acid more readily attacks cobalt, this again indicated that the cobalt atoms were distributed over all the crystals uniformly, the cobalt concentration in the 5% alloy being less throughout and the resistance to the acid hence greater. For comparison, a section of an annealed wire of pure platinum was similarly examined, and its microstructure was practically identical with that of the cobalt alloys. The alloys must, therefore, be solid solutions of cobalt in platinum, and the cobalt atoms in them isolated.

Platinum possesses a face-centered cubic lattice, while cobalt is hexagonal for lower temperatures and face-centered cubic at higher ones (about 600°C). As transformation points are generally rapidly lowered by alloying, e.g., the Curie point, these high-platinum alloys might be expected to have the cubic structure. High magnification (1300 times), revealed definite cubic formations in many of the crystals.

Recombination of Electron and Alpha-Particle

The writers have computed by quantum mechanical means the probability of recombination between an electron and a hydrogen atomic ion or an alpha-particle, when the final state is the hydrogen atom or

helium ion in some quantum state. The initial wave function used is that developed by Mott,¹ and represents a unidirectional

¹ Mott, Proc. Roy. Soc. A118, 542 (1928).

beam of electrons travelling toward a nucleus with velocity v . The final wave function is the usual one for the atom in one of its quantum states.

The matrix element of the moment corresponding to this transition is proportional to the target area of recombination, $q(v, \nu_i)$, discussed by Mohler.²

The calculations indicate that the target area for recombination of an electron and a nucleus of charge Ze is

$$q = 6.10 \times 10^{-11} Z^8 \exp \left[\frac{\pi k - 4k \tan^{-1}(1/k)}{v\nu^2 \sin h \pi k} \right]$$

where V is the electronic energy of motion relative to the nucleus in volts, ν is the frequency of the radiated light in wave-numbers, $k = 3.67 Z/V^{1/2}$, and the final state is the normal state. This agrees remarkably well with the theoretical and experimental formulas given in the recent summary by Seeliger.³ No approximations have been made in the derivation of this formula.

The q 's for the upper states are similar expressions, none of them showing any maxima in the range of V between zero and infinity. Therefore the maxima obtained by Davis and Barnes must be due to some mechanism involving more than one electron and one alpha-particle. The explanation offered by E. Q. Adams⁴ might be the correct one, despite

Barnes's⁵ objection. For the quantum mechanics indicates that processes not involving the electrical forces between the nuclei hold equally well for single nuclei, with the quantities giving the relative proportions of the resulting end products appearing as probabilities. In other words, if a stream of electrons falling on N alpha-particles creates n He⁺ ions in time t , then when this same stream of electrons falls on one alpha-particle, there is a probability n/N that this one alpha-particle will become a He⁺ ion in time t .

The authors have carried through this reasoning by probabilities from the beginning and have obtained an equation substantiating Adams's result. Since, however, the values of all the constants involved are not known, it is impossible to know at present whether this mechanism will account for the observed peaks.

BOOK REVIEWS

Müller-Pouillet's *Lehrbuch der Physik*. 11. Aufl. 2. band. *Lehre von der Strahlenden Energie (Optik)*. 2. Hälfte. 1 & 2. teil. KARL WILHELM MEISSNER, editor. Pp. xvi+xvi+929 to 2392. Figs. 625 to 1345. Friedr. Vieweg & Sohn, Braunschweig, 1929.

After some delay following the death of Dr. Lummer, the editorship of this standard text and reference work has been assumed by K. W. Meissner. Three times the bulk of the corresponding sections of the previous edition (1909), the new half-volume impresses one again with the rate at which the research workers in the field of optics have been outdistancing the publishers. The editor has carefully subdivided the field, and with the cooperation of several of the most able German physicists presents here a work thorough, well organized, and readable, that develops experimental and theoretical optics up to 1924-1925 and, in a few outstanding sections, further.

About a third of the space is given to spectroscopy, including chapters on spectroscopic apparatus and methods, by Meissner, Hettner, Czerny, and Gehrcke; series spectra, by Paschen; band spectra, by Kratzer; x-ray spectroscopy, by Coster; Zeeman effect, by Back; and the foundations of the quantum theory of atomic structure, by Pauli. The prospective reader who is led by the author's name and the publisher's date, to expect a unified present-day account of atomic theory in this last chapter, will be disappointed. There is an apology elsewhere (p. 1483) for this chapter, written in 1924, and there are excellent concise appendices on the introduction of the Goudsmit-Uhlenback magnetic electron and the fundamental work of Schroedinger and Heisenberg. But there is no sufficient excuse given for publishing, under the date 1929, of a good deal of obsolete material, in this chapter (e.g., Art. 11, *Die Grenzen der heutigen Form der Quantentheorie*) and others.

The older electromagnetic-optical phenomena are handled mainly by Buchwald and Ladenburg. Kohn has an exhaustive treatise on photometry.

J. E. MACK

PROCEEDINGS
OF THE
AMERICAN PHYSICAL SOCIETY

• MINUTES OF THE CHICAGO MEETING, NOVEMBER 29 AND 30, 1929

The 159th regular meeting of the American Physical Society was held in Chicago, Illinois at the Ryerson Physical Laboratory of the University of Chicago on Friday and Saturday, November 29 and 30, 1929. The presiding officers were Professor Henry G. Gale, President of the Society, and Dr. W. F. G. Swann, Vice-President.

On Friday evening the Physical Society had a dinner at the Quadrangle Club. There were about one hundred members present. The after dinner speakers were Dr. W. F. G. Swann, Dr. Dayton C. Miller and Professor A. J. Dempster.

At the regular meeting of the Council held on Friday, November 29th, 1929, one was elected to fellowship, one was transferred from membership to fellowship, and one hundred and fifty-two were elected to membership. *Elected to Fellowship:* John B. Whitehead. *Transferred from Membership to Fellowship:* William V. Houston. *Elected to Membership:* T. E. Allibone, Emerson D. Bailey, William Baldwin Jr., E. G. Bangratz, LeRoy L. Barnes, Milton Bergstein, Arthur Bernhart, Donald K. Berkey, Luther M. Bingaman, Francis Birch, Heaton P. Blakeslee, Charles D. Bock, Gilbert F. Boeker, Isabel Boggs, Thomas H. Briggs Jr., Leslie E. Brooking, William F. Brown Jr., O. H. Caldwell, C. Wesley Carnahan, A. B. Carr, Randle V. Cartwright, Margaret L. Clark, Philip Constantinides, Trevor R. Cuykendall, Beryl H. Dickinson, James F. Duncan, J. R. Dunning, M. A. Easley, Sister Mary Edwina, Alexander Efron, Charles D. Ellis, John H. Findlay, Arthur W. Fleming, Hazel M. Fletcher, Arthur E. Focke, J. Franck, Austin R. Frey, Harold Q. Fuller, James W. Givens Jr., A. T. Goble, Martin Grabau, Newton M. Gray, John P. Hagen, August Hagenbach, Sigmund Hammer, O. Philip Hart, Charles D. Hartman, Alexander Harvey, Clifford E. Harvey, Edgar R. Hauser, Thomas Hazen, C. M. Hebbert, Jesse C. Hendricks, Willard H. Hickok, A. F. Horlacher, D. S. Hughes, Lewis H. Humason, Malcolm C. Hylan, H. F. Kaiser, Roy J. Kennedy, W. Jay Kennedy, James R. Kershaw, George E. Kimball, Harold L. Knowles, Matsui Kumiyasu, A. M. Kuethe, Olive M. Lammert, Charles C. Lauritsen, Glenn Q. Lefler, Lewis Larrick, Urner Liddel, Tate Lindsey, Erwin F. Lowry, Janet M. MacInnes, Homer E. Malmstrom, Louis Marick, D. E. Marshall, Tanaka Masamichi, F. A. Maxfield, Ronald L. McFarlan, R. T. McGoldrick, Edwin M. McMillan, Harold Mestre, Earl R. Miller, John S. Millis, Carol G. Montgomery,

Howard R. Moore, Neal D. Newby, J. L. Nickerson, Foster C. Nix, Will V. Norris, Helen B. Notestein, Leonard M. Onsgard, Herbert N. Otis, F. L. Partlo, John V. Pennington, William M. Pierce, Milton S. Plesset, Richard G. Poindexter, Wilson M. Powell Jr., Simeon A. Ratner, John J. Rheins, Charles E. Rich, Donald E. Richardson, H. P. Robertson, Walter W. Roehr, Harry Rolnick, Donald C. Rose, Jenny Rosenthal, Philip W. Rounds, Edward W. Samson, A. Sandow, S. P. Sashoff, Edwin G. Schneider, Harold F. Schwede, Raymond W. Sears, Shirleigh Silverman, William W. Sleator, F. Raymond Smith, John F. Smith, Letha A. Smith, David L. Soltau, Wayne T. Sproull, John R. Stehn, Louis Strait, Kuno Takuji, Tutomu Taraka, John B. Taylor, James S. Thompson, John A. Tiedeman, John S. Tobin, John W. Todd, A. H. Toepfer, Charles B. Vance, Robert J. Van de Graaff, Frank L. Verweibe, Alice M. Vieweg, Donald S. Villars, Worth Wade, Henry Walther, William H. Watson, Wayne Webb, Max Wehrli, Thomas W. B. Welsh, W. W. Wetzell, Mary A. Wheeler, John L. Wilson, E. O. Wollan, Ralph W. G. Wyckoff, Imaoka Yoshio, Suga Yosuke, and Rolland M. Zabel.

The regular scientific session consisted of forty-two papers, five of which—Nos. 1, 16, 17, 21, 38—were read by title. The abstracts of these papers are given on the following pages. An AUTHOR INDEX will be found at the end.

W. L. SEVERINGHAUS, *Secretary*

ABSTRACTS

1. Thermal expansion of "Carboloy." PETER HIDNERT, *Bureau of Standards*. Measurements have been made on the linear thermal expansion of two samples of "Carboloy" (a new tool material) purchased several months ago from Carboloy Company, Inc., 350 Madison Ave., New York City. An interferometer was used in the determinations at various temperatures between 20° and 400°C. The following results were obtained.

Sample	Heating	Average Coefficients of Expansion per Degree Centigrade				
		20 to 60°C $\times 10^{-6}$	20 to 100°C $\times 10^{-6}$	20 to 200°C $\times 10^{-6}$	20 to 300°C $\times 10^{-6}$	20 to 400°C $\times 10^{-6}$
1374 I	First	5.2	5.3	5.5	5.6	5.9
	Second	5.1	5.2	5.6	5.7	6.0
1375 I	First	5.0	5.2	5.5	5.8	6.0
	Second	4.9	5.2	5.5	5.8	6.0

The coefficients of expansion of "Carboloy" are larger than the corresponding coefficients of tungsten. For the range from 20° to 400°C, the average coefficient of expansion of the two samples of "Carboloy" is approximately 30 percent greater than the coefficient of expansion of tungsten.

2. Young's modulus determined with small stresses. DAROL K. FROMAN, *University of Chicago*. (Introduced by A. J. Dempster.)—An interferometer method, similar to that used by E. G. Grüneisen (*Ann. d. Physik* **22**, 801, (1907)), was used to determine the extensions of metallic rods under small stresses. The applied stresses ranged in value from less than 1 kg/cm² to the smallest usually used in commercial testing, about 300 kg/cm². For the substances examined, Young's Modulus was found to increase very rapidly as the stress increased from zero, to reach a maximum at a comparatively small stress, and then to decrease almost exponentially to the ordinary value. The maximum elasticity was found to be from 10 to 30

percent higher than that at large stresses. The annealing of the rods is probably connected with this divergence from Hooke's Law with small stresses, as slight differences were found on reannealing some of the rods.

3. The construction of a master clock with light controlled contacts. J. V. HOFFACKER, *Purdue University*. (Introduced by K. Lark-Horovitz.)—Mercury contacts for controlling circuits periodically by means of pendulums, because of their unreliability and their effect on the period of the pendulum, have been replaced by photoelectric cells influenced by beams of light interrupted periodically by the swinging pendulums. But since selenium cells are equally sensitive to light when operating with direct or alternating current they can be used with a specially constructed relay employing alternating current from lighting mains as the only source necessary. Low resistance selenium cells transformer coupled and high resistance cells as grid leaks in triodes have been used successfully. The relayed current rectified by a dry rectifier is used to keep the pendulum itself going so that no clockwork is necessary to operate repeater clocks.

4. The Nernst heat theorem. HERBERT J. BRENNEN, *Northwestern University*. The Gibbs-Helmholtz equation requires that the limit of $(\partial U/\partial T)=0$, as T approaches zero. Nernst makes the further assumption that the limit of $(\partial A/\partial T)=0$, as T approaches zero. On putting: $U=U_0-bT^2-2cT^3$ -etc., integrating the Gibbs-Helmholtz equation and using Nernst's assumption, one finds: $A=U_0+bT^2+cT^3$ +etc. Whence, $Q=A-U=2bT^2+3cT^3$ +etc.; where A , Q , U and T have their usual significance. Hence, for small values of T , as a first approximation: $(\partial \log Q/\partial \log T)$ is equal to two, which is double that demanded by the Carnot heat theorem. In order to account for this discrepancy, it is suggested that: (1) since U is a function of the volume as well as the temperature, both U and T be regarded as independent variables and A , a dependent variable; (2) the Gibbs-Helmholtz equation be generalised to: $A-U=T(\partial A/\partial T)+KU(\partial A/\partial U)$ where K is a constant. This equation becomes identical with that of Gibbs and Helmholtz when $U=0$ or when A is independent of U .

5. Porous plug measurements with air. J. R. ROEBUCK, *University of Wisconsin*.—In an earlier article (Proc. Amer. Acad. 60, 537, (1925)) I described apparatus and methods used for measuring the Joule-Thomson coefficient over 25 to 280°C and 1 to 215 atm. The present work extends the data down to -150°C. The measurements give isenthalpic curves in a pressure-temperature field. The derivative $(dT/dp)_h=\mu$ =Joule-Thomson coefficient has been plotted as a function of p and T over the whole field. The original curves were used to spread C_p at 1 atm. over the 215 atm. range. With the aid of data on (pv) for air taken from the literature, the free-expansion (Joule) coefficient $(dT/dp)_u=\eta$ has been calculated over -100° to +200°C and 1 to 100 atm. These again give the elastic coefficient $1/v(dv/dp)_t=\gamma$ and $(du/dv)_t=\lambda$ over this field. λ can be used to calculate the correction to the constant volume air temperature scale, which is being done. This completes the work with air, and the apparatus is being rebuilt into a closed system to measure pure gases of which the first is to be helium.

6. The function of the base metal in oxide coated filaments. E. F. LOWRY, *Westinghouse Elec. & Mfg. Co., East Pittsburgh*.—Measurements on a number of UX-281 Radiotrons with oxide coated platinum-iridium filaments and others having oxide coated "Konel" filaments show that the base or core metal plays an important part in the behavior of such filaments. Konel, an alloy of nickel, cobalt, iron and titanium, has a much higher thermal emissivity than platinum and therefore, when operated at 4 watts per cm², reaches a temperature about 150°C lower than that reached by oxide coated platinum with the same energy input. Nevertheless, oxide coated Konel filaments give slightly higher emissions than oxide coated platinum filaments under like conditions of input energy. This anomalous behavior requires a modification of the present theory of oxide emission. This requirement is met by assuming that the source of the electron emission is a layer of metallic barium in contact with the base metal and that the electrons diffuse through the pores in the oxide coating which is a rather good non-conductor. This hypothesis serves as a satisfactory basis of explanation for the varied and somewhat confusing phenomena of oxide emission.

7. Photoelectric behavior of solid and liquid mercury. DUANE ROLLER, *University of Oklahoma*.—With monochromatic light, the photoelectric threshold for solid mercury, freshly distilled in vacuum, was found at $2750 \pm 25\text{Å}$ for all temperatures between -190°C and the melting point. The threshold for liquid mercury at room temperature was at $2735 \pm 10\text{Å}$, confirming the value established earlier by Kazda and by Hales. The emission for monochromatic light was independent of the temperature between -190° and -40°C . There was no indication of a change in the crystal structure of mercury in this region of temperatures. The emission for the solid phase was always somewhat higher than that for the liquid at room temperature, possibly due in part to a change in the optical absorptivity of the mercury surface with change in phase. A study of the optical absorptivity of solid mercury is in progress. Between -39° and 0°C the emission was about 75 percent of that at room temperature but showed hysteresis with successive warming and cooling of the mercury. Thus a further study of liquid mercury between melting and room temperatures is needed. Most of this work was done at the California Institute of Technology.

8. Spatial distribution of photoelectrons. S. SZCZENIOWSKI, (*International Education Board Fellow*) *University of Chicago*.—The perturbation of a hydrogen-like atom by a plane polarized electromagnetic wave is considered on the basis of Dirac's equations, and perturbed wave-functions are obtained. These functions lead by a method similar to that used by Sommerfeld in his "Wellenmechanisches Ergänzungsband," to a formula for the spatial distribution of the photoelectrons, but differing from his in the first approximation, by a factor equal to $5/9$. This factor follows from a consideration of the normalization factors for the spherical harmonics, which were not introduced by Sommerfeld. A second approximation has also been obtained showing the influence of electron spin. This formula differs from that obtained by Carrelli (Zeits. f. Physik 56, 694, (1929)) in that the spin and some other terms not considered by Carrelli appear.

9. Electron velocities in an electrodeless discharge. CHARLES J. BRASEFIELD, *University of Michigan*.—A high frequency discharge in hydrogen was obtained by applying high frequency voltages to the movable external electrodes of a cylindrical discharge tube. By observing the change in the ratio of the densities of certain singlet and triplet lines of the secondary spectrum (see Phys. Rev. 34, 437 (1929)), the mean electronic velocity in the discharge was studied as a function of (1) the frequency of oscillation, (2) voltage between electrodes, (3) distance between electrodes and (4) gas pressure. Observations were made at frequencies of oscillation corresponding to the wave-lengths 15, 25, 50, 100 and 200 meters. For example, at 0.03 mm pressure with 1400 volts applied to the electrodes, the electronic velocity increases from 23.7 volts at 25 meters to 25.8 volts at 200 meters. At 25 meters and 0.03 mm pressure, the electron velocity increases from 20.8 volts to 23.7 volts as the voltage between electrodes is increased from 500 volts to 1400 volts. Finally, at 25 meters with 1000 volts between electrodes, the electron velocity increases from 22.7 volts to 24.7 volts as the pressure is reduced from 0.06 mm to 0.01 mm. It appears that conditions in the electrodeless discharge should be quite similar to those in the positive column of an ordinary Geissler tube discharge. This probably explains why such small changes in electronic velocity were observed.

10. Motion of electrons in carbon monoxide. H. B. WAHLIN, *University of Wisconsin*.—In a paper which appeared in an earlier issue of the Physical Review [21, 517 (1923)] it was shown that the mobility of electrons in CO obey the equation $U = A/[B + V]^{1/2}$ with a high degree of accuracy. Shortly after the appearance of this paper K. T. Compton showed that the equation for the mobility should be of the form $U = A/[1 + (1 + BV^2)^{1/2}]^{1/2}$. Application of this equation to the data presented earlier shows that for low fields the Compton equation holds within the limits of experimental error. At values of X/P above 0.4 volts/cm/mm pressure a systematic deviation from this equation appears due probably to a decrease in the electronic free path with increasing electron velocity. The electron free path in thermal equilibrium with the gas and at a pressure of 1 mm is found to be 0.069 cm.

11. Slow caesium ions in hydrogen and helium. J. S. THOMPSON, *University of Chicago*, (Introduced by A. J. Dempster).—The motion of positive caesium ions in hydrogen and helium has been examined for ion velocities ranging from 3 to 600 volts. Three different experimental arrangements were used in which the ions traversed a known gas path and in which any weakening of the bundle could be observed. No absorption of 10 to 600 volt ions was observed for gas pressures up to 0.030 mm of Hg. At the highest pressure the ions make 20 collisions without deflections from their original directions. Below 10 volts and for pressures above 0.010 mm a definite weakening of the bundle sets in and increases rapidly with the pressure. In all cases studied the ions were retarded, and the velocity distribution produced has been measured. The final velocities show an approximate probability distribution about a mean retardation. This distribution becomes more nearly that of the error curve for smaller velocities and higher pressures. The large absorption of the caesium ions observed by Ramsauer is accounted for on the basis of this retardation. Lithium ions in helium show considerable scattering which decreases as the velocity is increased and rises rapidly as the velocity is reduced below 50 volts.

12. Ionization efficiency of electrons in potassium vapor. J. KUNZ AND A. HUMMEL, *University of Illinois*.—Using a direct method in which a beam of electrons is projected into a field-free chamber, the number (N) of positive ions formed per electron per centimeter path per unit pressure has been measured and plotted against the energy of the primary electron. Scattering of the primary beam was prevented by means of a magnetic field of 350 to 400 gauss parallel to the beam. A small transverse electric field was employed to drive the positive ions to the collecting plate. Two other plates served to make this field uniform in the region from which the ions were collected. For potassium vapor N was found to have three maxima occurring at 40, 81, and 122 volts accelerating potential. The second and third maxima are respectively 18 percent and 11 percent greater than the first. N is approximately 20 times the value of N for argon. The curve for argon has a maximum value for N of 0.108 appearing at 88 volts which compares with the maximum 0.113, at approximately 125 volts, observed by Compton and Van Voorhis.

13. A study of the ions produced in mercury vapor by electron impact. WALKER BLEAKNEY, *University of Minnesota*.—In a recent paper (Phys. Rev. 34, 157 (1929)) a method was proposed for analyzing the primary results of ionization by electron impact. The method has been applied to a quantitative study of the five mercury ions Hg^+ , Hg^{2+} , Hg^{3+} , Hg^{4+} and Hg^{5+} . The results show that the fraction of the current carried by the Hg^+ ion falls rapidly from 100 percent at electron velocities between 10.4 and 30 volts to about 70 percent at 100 volts, and then approaches a nearly constant value of about 60 percent for increasing electron speeds. At 300 volts the fractions of the total positive ion current carried by the five ions, in order, are 59, 26, 11, 3.5, and 0.5 percent respectively. The results have been reduced to number of ions per electron per cm path per mm pressure at 0°C as a function of the electron velocity. These data show a distinct maximum of magnitude about 21 for the Hg^+ ion in the neighborhood of 50 volts while the value at 300 volts has dropped to half as much. Maxima also appear for Hg^{2+} and Hg^{3+} at 115 and 210 volts respectively.

14. Absorption of lithium ions in mercury vapor. I. W. COX, *University of Chicago*, (Introduced by A. J. Dempster).—The absorption of 25 to 300 volt lithium ions in passing through mercury vapor at various pressures up to 48×10^{-4} mm was observed by two different methods. In the first method the ions described a semicircular path in a magnetic field and the decrease as the pressure was increased was observed. In the second method the ions, after this magnetic analysis, described a straight path to a collecting chamber and the decrease in the number entering the circular aperture of the collecting chamber was observed as the pressure was increased. A consistent difference was found in the absorption coefficients given by the two methods. It was also altered by a change in the aperture of the collecting chamber in method 2. This indicates that the collisions with the mercury atoms are not elastic, but that a large fraction of the deflections are through small angles. Ionic diameters deduced from the absorption depend on the apertures of the apparatus used. The ions collected are not slowed

up appreciably, and there is a dependence of the absorption observed with any particular aperture on the velocity of the ions.

15. The reflection of lithium ions from metal surfaces. R. B. SAWYER, *University of Chicago*. (Introduced by A. J. Dempster.)—Experiments have been performed on the reflection of lithium ions from reflectors of platinum foil and of nickel crystals deposited on tungsten foil (Rupp, *Ann. d. Physik* [5], 1, 801 (1929)). Movable ground joints in the tube were entirely eliminated. Readings were taken with both cold and hot reflectors. Spodumene was used as a source of ions and reflection was studied in the meridian plane only. Superposed on a diffuse scattering of ions were two reflected beams. One was reflected nearly specularly, as found by Read (*Phys. Rev.* 31, 155 (1928)) and Gurney (*Phys. Rev.* 32, 467 (1928)), the angle of maximum reflection, however, being independent of accelerating potential. The other beam appeared only at voltages above 200 or 250 and was composed of ions most of which had retained 80 percent or more of their original energy. This beam was found between the incident beam and the normal to the surface, at angles independent of the accelerating potential up to 700 volts. This independence of angle on voltage forbids diffraction interpretations. A tentative explanation consists in supposing specular reflection from the (110) planes of the nickel crystals, but the agreement is not entirely satisfactory.

16. Secondary emission of nickel under positive ion bombardment in the positive column in neon. W. UYTERHOEVEN AND M. C. HARRINGTON, *Princeton University*.—An attempt is made to measure the secondary emission under positive ion bombardment of metal collectors in the positive column under conditions as near as possible to those in the cathode fall. A combination of a fixed collector and a movable one opposite the first, was used. The movable one was given a negative potential and the ion current to it compensated; then the potential of the fixed electrode was varied and the corresponding change in current to each measured. The results obtained so far show that for an accelerating potential of about -150v , the secondary emission can reach 50 p.c. of the total current collected on a negatively charged electrode. (*Proc. Nat. Ac. Sc.* 15, 32 (1929)). The electron mean free path seems to depend markedly on the degree of ionization of the gas, the measured values being less than the gas kinetic values (e.g. 50 p.c.). A large fraction of the electron emission from the metal is apparently due to the impact of metastable atoms on the collector. (Oliphant, *Proc. Roy. Soc. A* 124, 228 (1929)), but for higher accelerating potentials of the positive ions their effect becomes more and more important (Penning, *Physica*, 8, 13 (1928)).

17. Zeeman effect in $\lambda 5211$ MgH band. G. M. ALMY, F. H. CRAWFORD AND E. L. HILL, (*National Research Fellow*), *Harvard University*.—The Zeeman effect for molecules lying between Hund's cases (a) and (b) has been treated theoretically by the quantum mechanics, and the results applied to the MgH band at $\lambda 5211$. For states near case (a) the theory predicts the usual splitting into $(2J+1)$ magnetic substates. When the magnetic separations are comparable with the doublet separations (very high fields or small doublet intervals) a Paschen-Back effect sets in corresponding to uncoupling of the electronic spin and the rest of the molecule with a degeneration of the term system into that of a symmetrical top superposed on that due to practically free spin. In a $^3\Sigma$ state (neglecting rho-type doubling) this degeneration is sensibly complete at all fields. The theory is verified quantitatively in the $\lambda 5211$ MgH band. In the earlier lines the size of the fine structure patterns agrees numerically with calculations. In the higher lines the Paschen-Back effect causes a filling in of the normal doublet interval with an unresolved band in addition to the appearance of outer wings which move out and become fainter with field. Pattern widths, separation of components, and line displacements, where observable, have been measured from plates taken at fields between 5000 and 28000 gauss. No detailed intensity calculations have been made.

18. A magneto-optic method of chemical analysis. FRED ALLISON AND EDGAR J. MURPHY, *Alabama Polytechnic Institute*.—This is a refinement of a method previously reported by one of us (Allison, *Phys. Rev.* 30, 66 (1927) and 31, 313(A) (1928)). Each chemical compound produces a minimum of light at a point characteristic of the compound. The surprising result

has been found that this characteristic minimum does not disappear until the concentration has been reduced to less than one part in 10^{10} . The method thus affords a very sensitive and rapid means of chemical analysis. A large number of such analyses has been made. The presence of compounds, instead of elements, is detected. Each inorganic compound is characterized by either a single minimum or two or more close minima. The number of these minima, with few exceptions, is the same as the number of known isotopes of the metallic element of the compound. The investigations have been confined to a number of organic liquids and an extensive series of nitrates, chlorides, sulphates and hydroxides in solution. The positions of the minima are some inverse function of the chemical equivalent of the metallic element of the inorganic compounds. The effect is no doubt a time effect, but a complete interpretation must await further investigations, which are in progress.

19. The absorption spectrum characteristic of vitamin A. JAY W. WOODROW AND H. L. CUNNINGHAM, *Iowa State College*.—The absorption spectra of substances containing vitamin A were obtained in the region from 290 to 350 $m\mu$ by means of a sensitive photoelectric spectrophotometer. Fresh cod-liver oil and spinach juice gave prominent absorption bands with maxima at 310 and 326 $m\mu$ with minor bands at 320, 330 and 337 $m\mu$. When the oils were extracted with ether, the bands were shifted toward the shorter wave-lengths by 3 $m\mu$ but their relative intensities remained the same. These bands were obtained with cod-liver oil, spinach juice, egg yolk and butter, all of which are known to be rich in vitamin A. Peanut oil which is rich in vitamin D but contains no vitamin A, gave the characteristic vitamin D bands at 270, 280 and 290 $m\mu$ but gave no indication of the bands in the neighborhood of 326 $m\mu$. Bubbling air through the cod-liver oil at a temperature of 90°C for an hour or exposing it to the ultra-violet light from a quartz mercury arc for 20 min., either of which will destroy most of the vitamin A, caused the disappearance of the absorption bands at 310, 320, 326 and 330 $m\mu$.

20. A new absorption band of atmospheric oxygen and the vibrational frequency of the normal molecule. HAROLD D. BABCOCK, *Mount Wilson Observatory*.—Four possible absorption bands in the "atmospheric" system of oxygen have been sought with air paths of 40 to 70 kilometers, (0, 1), (2, 1), (2, 2), (1, 1). The last has been discovered; the others are not yet established. The intensity of (1, 1) is roughly 1/2500 that of (0, 0). Over 30 lines are identified and 26 are accurately measured. Wave-number differences are taken from these to corresponding lines in (0, 0), (1, 0), (2, 0) and (3, 0). Eliminating the rotational effect and using the known spacing of the vibrational levels in excited O_2 , these combinations give $1556.31 \pm 0.05 \text{ cm}^{-1}$ as the most probable value of the vibrational frequency of the normal molecule having 1 unit of vibrational energy. Results from *P* branches are more concordant than from *R* branches, which show a slight linear dependence on the upper vibrational state. The new value is compared with the Raman displacement, and its usefulness is discussed in other relations such as, calculation of isotopic displacement and of heat of dissociation. The data also help to establish a test for the consistency of solar standards of wave-length.

21. On the active nitrogen glow. RICHARD RUEDY, *Toronto*.—With strong afterglows in N_2 the 3 prominent bands can be seen for several seconds; such a persistence is longer than the time necessary for the recombination of N atoms (the formation of H_2 being taken as a basis of comparison) and considerably longer than the life of metastable systems. However, the potential energy curve for the initial state of the afterglow bands shows that, although emission of light takes place when during their oscillations the atoms have reached their greatest elongation, dissociation is likely to occur at the inner turning point, particularly for the smaller heats of dissociation which have found favor since it was shown that no Xe lines could be obtained in the afterglow, (*Trans. R. Soc. Can.* **22**, 303 (1928)). This dissociation process provides for the afterglow the necessary number of atoms, and eventually for metastable atoms. The real excitation potential of level *A* seems to be below 7 volts. In a 1 to 2 l bulb an initial intensity of the glow, corresponding to about one candle, can be obtained at a few mm Hg, and a total intensity of a few candles. This corresponds to 10^{17} emission processes initially, or to 10^{14} radiating molecules per cm^3 (10^{-3} mm Hg), an insufficient amount for ordinary absorption measurements.

22. The excitation of certain nitrogen bands by positive ion impact. H. D. SMYTH AND E. G. F. ARNOTT, *Princeton University*.—In the sources of light usually used for the study of band spectra excitation is chiefly by electron impact. It is now generally agreed that an electron impact does not alter the rotational nor vibrational momentum of a molecule. However, it might be expected that in excitation by positive ion impact both the vibrational and rotational momentum might be altered. We have, therefore, undertaken the study of the intensities of band spectra excited in nitrogen by the impact of mercury ions. Mercury canal rays pass through the cathode of a discharge tube into an atmosphere of nitrogen. The feeble light excited is found to consist almost exclusively of the negative nitrogen bands. In the two bands ($\lambda 4278$ and $\lambda 3914$) which have been photographed with a small grating, the lines corresponding to the lowest rotational states are definitely weaker than in comparison photographs taken with an electrodeless discharge. In fact the first two lines of the *R*-branch and the first line (perhaps the first two) of the *P*-branch are entirely missing. Theoretically one might expect one more line of the *P*-branch than of the *R*-branch to be missing. The investigation is still in a very preliminary stage.

23. The spectrum of singly ionized indium. R. J. LANG, *University of Alberta* AND R. A. SAWYER, *University of Michigan*.—The indium spectrum has been excited in a hollow cathode discharge in helium, using the same technic as in the authors' previous work with gallium. The spectrum has been photographed throughout the entire photographic region. The first spark spectrum is a two electron spectrum with singlet and triplet terms of which the chief combinations have been identified. Enough higher terms have been found to permit the calculation of approximate term values. The deepest term, $(5s^2)^1S$, is placed at 152350 cm^{-1} corresponding to an ionization potential of 18.81 volts.

24. Intensity measurements in neon spectrum. H. N. SWENSON, *University of Illinois*.—The Ornstein method of photographic photography has been applied to a study of the neon discharge. Special emphasis was placed upon elimination of errors in the optical system and in the development of plates. Density screens were prepared by sputtering platinum films of various densities on quartz plates. This screen was placed in an optical system similar to that of Ornstein and vibrated electrically to eliminate possible errors due to non-uniformity. Development was carried out at constant temperature and with forced circulation of developer around the plate. Intensity ratios were obtained for 19 lines in the region from 5800\AA to 6700\AA . The discharge was excited by a 10,000 volt transformer, the pressure being 2 mm. The intensity ratios for multiplets which are transitions from the same upper level, are not in agreement with the values of Dorgelo or those predicted by the Ornstein-Burger intensity rules, but show marked agreement with values recently published by Ende using electron impact excitation.

25. Intensity relations in some of the stronger multiplets of chromium I and chromium II. CEDRIC E. HESTHAL, *Ohio State University*.—The relative intensities of thirteen multiplets in the spectrum of chromium I and of five multiplets in the spectrum of chromium II have been determined by photographic photometry. The method used was that described by G. R. Harrison in the *Journal of the Optical Society* (17, 389 (1928); 18, 287 (1929)). Numerous violations of the intensity formulas which have been derived by H. N. Russell, R. de L. Kronig and others are found. In some multiplets all the lines appear anomalous while in other multiplets only a fraction of the lines are abnormal. In general, the violations are more numerous than those observed by Harrison in titanium and fewer than those observed in iron and nickel by Ornstein, showing that perturbations increase with atomic number among the elements of the iron group. The intensities of multiplets forming two triads have also been determined and the equivalent excitation temperatures for these calculated. For one of these triads the method fails showing that this triad does not obey the formulas of R. de L. Kronig while for the other, temperatures between 2800°K and 4800°K were observed for different exposures. Data have been obtained to show that the equivalent excitation temperature is not the same for multiplets having final states in different regions of the atom.

26. Relations between hyperfine structure separations. S. GOUDSMIT AND R. F. BACHER, *University of Michigan*.—The quantum mechanics conception of a spinning electron in an s -state makes it probable that its interaction energy with a nuclear moment i is simply proportional to the average of $i \cos(i \cdot s)$. In some cases where the hyperfine structure is mainly caused by an s -electron one can evaluate this cosine. This gives relations between the hyperfine structures of different levels which agree well with observations on Tl II (McLennan).

The large hyperfine structures in Tl II are due to the presence of the deeply penetrating single $6s$ -electron, those of Tl I are much smaller ($6s^2$). In Tl III only the normal state $6s$ will show a very large hyperfine structure which must be about 8 cm^{-1} . In more complicated cases one can only tell that the interaction energy will be proportional to $ij \cos(i \cdot j)$ which causes the interval rule to be valid for hyperfine structure.

27. Relativity transformation of an oscillation into a traveling wave, and de Broglie's postulate in terms of velocity angle. VLADIMIR KARAPETOFF, *Cornell University*.—The author has previously described a method of representation of space-time relationships in restricted relativity, by means of oblique coordinates (J.O.S.A. and R.S.I. 13, 155 (1926)). The theory has been applied to the following problem: Two observers, S and S' , are moving at a relative velocity q . The S' observer has in his system a set of pointers oscillating in synchronism and in phase with one another. It is required to describe the motion as seen by the observer S . By drawing two sine waves in the Lorentzian plane, it is shown graphically that for the S observer the pointers do not swing in synchronism, but form a traveling wave whose velocity of propagation, u , is connected with q by the familiar relationship $uq = c^2$, where c is the velocity of light.

Introducing the so-called velocity angle, α , determined by the relationship $\sin \alpha = q/c$, various other properties of the traveling wave, as seen by S , have been deduced, such as the apparent frequency at a point in space, the apparent amplitude and its velocity of propagation, the Fitzgerald contraction of the oscillating system, the slowing down of the frequency of oscillation, the group velocity of "super-light" waves, and de Broglie's quantum principle. The article appeared in the *Journal of the Optical Society of America* for November, 1929.

28. The significance of the Michelson-Morley-Miller experiments in relation to the restricted theory of relativity. W. F. G. SWANN, *Bartol Research Foundation*.—While aether drift experiments originally suggested the line of thought which leads to the formulation of the restricted theory of relativity, it would seem that the fundamental significance of that theory does not depend primarily upon these experiments. The most logical origin of the transformation of the restricted theory is to be found as a special case of the general theory, and the purpose of the present paper is to show how, with this in view, the fundamental working content of the restricted theory, the invariance of laws under the Lorentzian transformation, is something which has no fundamental relation to the question of whether the aether drift experiments do or do not give a positive result.

29. Electron distribution in magnesium oxide. ERNEST O. WOLLAN, *University of Chicago*. (Introduced by A. H. Compton.)—The intensity of x-rays reflected from powdered crystals of magnesium oxide were measured for all lines out to $\theta = 45^\circ$. The values of the structure factor, F , were calculated and plotted against $\sin \theta$. Using the values of F from this curve as coefficients in the Fourier Series given by Compton ("X-Rays and Electrons") the radial electron distribution for the atoms of magnesium and oxygen was determined. The electron distribution curves for these atoms are very similar to the curves by Havighurst (Phys. Rev. 29, 1 (1927)) for NaCl and NaF. However, the data indicate that the number of electrons associated with magnesium and oxygen is more nearly that of the neutral atoms than that of the ions, whereas Havighurst concludes that the lattice points are occupied by ions. A recalculation of some of Havighurst's data brings results which are in closer agreement with those of the author.

30. The efficiency of x-ray fluorescence. A. H. COMPTON, *University of Chicago*.—A review of the published data describing the intensity of fluorescent x-rays shows that the various observers agree that the number of quanta of fluorescent x-rays emitted by a radiator is con-

siderably less than the number of quanta which it absorbs from the primary beam. The values of the efficiency of fluorescence that appear in the literature are for the most part, however, found not to be quantitatively reliable. New experiments give values of the "fluorescence yield," or ratio of the number of fluorescent K quanta to the number of photoelectrons ejected from the K shell, of 0.68 for a molybdenum radiator, 0.56 for bromine, 0.54 for selenium, and 0.37 for nickel. The values seem to be independent of the wave-length of the exciting rays. These measurements agree within experimental error with Auger's values of the fluorescence yield, based on his count of the frequency of occurrence of the compound photoelectric effect, and thus indicate that it is this effect which makes the fluorescence yield less than unity. Knowledge of the fluorescence yield gives an expression for calculating the relative intensity of two x-ray beams of different wave-length, in terms of the ionization currents obtained, and other factors.

31. Efficiency of production of continuous spectrum x-rays. WARREN W. NICHOLAS, *Bureau of Standards*.—There is a large discrepancy between the efficiency estimated by Kulenkampff (*Handbuch der Physik* vol. 23), who found $k=8\pm2\times10^{-10}$ in the formula, $\text{efficiency}=kZV$, where Z is the atomic number of the anticathode material and V is the potential across the tube in volts and the more recent experimental determination by Rump, who found k to be about 15×10^{-10} . This discrepancy makes desirable a closer consideration of some of the secondary processes (reflection of cathode rays from anticathode, etc.) occurring in both gas filled and hot cathode x-ray tubes, as well as a further examination of corrections for absorption (including absorption in the anticathode) and for asymmetric spatial distribution of x-ray energy. A correction of Rump's data on this basis leads to a value of k about 10×10^{-10} . Some estimates of actual x-ray energy, both continuous and characteristic, obtained outside a tube are obtained incidentally.

32. Absolute measurement of certain x-ray wave lengths. J. M. CORK, *University of Michigan*.—An x-ray vacuum spectrograph employing a plane glass grating 30,000 lines per inch and having a distance between grating and photographic plate of one meter has been used to obtain the absolute wave-length value of the L -series emission lines for elements molybdenum (42) to antimony (51). In addition many other lines are present due to extraneous sources in the x-ray tube. These wave lengths have been previously accurately measured by many observers employing the crystal method. A comparison of the two sets of values is made bearing on the question regarding the Avogadro number and electronic charge. The results obtained for the wave-lengths of the two molybdenum lines $L\alpha$ and $L\beta_1$, are respectively 5.3943 and 5.1658 A.U., indicating for e the value 4.821×10^{-10} e.s.u.

33. The index of refraction and absorption coefficient of gold for the $K\alpha$ line of carbon. ELMER DERSHEM, *University of Chicago*.—An experimental curve showing the intensity of reflected radiation plotted against glancing angle of incidence was obtained for a sputtered gold surface and the $K\alpha$ line of carbon ($\lambda=44.6\text{\AA}$) by the use of methods and apparatus previously described (*Phys. Rev.* 34, 1015 (1929)). The absorption coefficient (μ) of gold leaf for this wave-length was measured and a value of the extinction coefficient (κ) determined from the relation $\kappa=\mu\lambda/4\pi$. The experimental value being $\kappa=0.0086$. A computation by the use of the Drude-Lorentz dispersion formula gives $1-n=\delta=0.009$ for the case of gold and this wave-length. These values of κ and δ were substituted in a modified form of the Fresnel reflection equations and a theoretical curve relating reflected intensity and glancing angle was thus obtained. To secure perfect agreement with the experimental curve either κ or δ or both must have smaller values. Hence curves are also computed with various pairs of arbitrarily assigned values of κ and δ which show the effect of changes in the values of these constants upon the theoretical curve.

34. Diffraction of x-rays in liquids and the effect of temperature. E. W. SKINNER, *University of Iowa*.—Fourteen liquids have been examined for x-ray scattering both at room temperature and close to their boiling points. Results for principal maxima are as follows: 1. Change in intensity. a. Heptylic acid, cyclohexane, benzene, octane, lauryl alcohol, and 2-7 dimeth-

ylactane show a decrease in intensity with increase in temperature. b. Mesitylene, di-n-propyl carbinol, tertiary butyl alcohol, 4 hydroxy 1-3 dimethylbenzene, 2 hydroxy 1-3 dimethylbenzene, 2-2-4 trimethylpentane, phenol, and naphthalene show an increase in intensity with increase in temperature. 2. An increase in molecular dimensions at higher temperatures was found, and, in general, the change is in agreement with the expected change in density due to expansion. 3. Change in peak width. The large peak common to all liquids thus far examined in this laboratory, appears to be wider at higher temperatures in all cases which is in agreement with existing theories of temperature effect in crystal scattering. All results are shown to be in agreement with the theory of the cybotactic condition except that an additional effect is needed to account for (1b).

35. Polarization of x-rays from thin aluminium anti-cathodes. BALEBAIL DASAN-NACHARYA, *University of Chicago*. (Introduced by A. H. Compton.)—An electron-beam 5 mm in diameter falls on thin aluminum foils of thickness varying from $6-250 \cdot 10^{-8}$ cm, mounted on a cylindrical frame-work attached to a glass tap and regulated from outside. A graphite plate on an ionization spectrometer served to measure the polarization. The voltages varied from 27-56 KV. For a given voltage, polarization increases slowly at first with diminution of thickness but rises exponentially for thicknesses smaller than $2.5 \cdot 10^{-4}$ cm. For different voltages the form of the curves remains the same, but the value of the polarization slightly diminishes with increase of voltage. The maximum polarization obtained was 47.5 percent. It looks likely that for a thickness of about $5 \cdot 10^{-6}$ cm the polarization would be complete.

36. A relation between the Compton effect and the diffraction by electrons. JAKOB KUNZ, *University of Illinois*.—In the Compton effect a quantum of radiation of momentum $h\nu/c$ is transformed into the momentum of an electron mv and into a weaker quantum of radiation of momentum $h\nu'/c$. If we assume that the reversed process also is possible and that an electron strikes a quantum head on, then we obtain: $mv = h\nu'/c = h/\lambda$, or $\lambda = h/mv$, which is the relation given by wave mechanics for the diffraction of electrons.

37. Paschen-Back effect of hyperfine structure. S. GOUDSMIT AND R. F. BACHER, *University of Michigan*.—By replacing the quantum vectors (s, l, j) and the magnetic moments (sg, lg, jg), of the ordinary multiplet theory by those of the hyperfine structure theory ($i, j, f; ig, jg, fg$), it is possible to adapt the work of Heisenberg, Jordan and Darwin on Zeeman effect and intensities in any field strength, to the study of the Zeeman effect of hyperfine structure. The thallium line ($6p^2P_{1/2} - 7s^2S_{1/2}$) $\lambda 3776$ is an example of incomplete Paschen-Back effect which can be treated quantitatively with the above method. The calculated splitting up of this line in a field of 43350 gauss is in cm^{-1} . $-3.00, -2.52, (-1.43), -(1.20), (+1.28), (+1.36), +2.45, +3.08$. Measurements by Professor E. Back and Dr. J. Wulff at Tuebingen give $-3.02, -2.54, (-1.42), (-1.22), (+1.35 \text{ strong}), +2.43, +3.10$. Without hyperfine structure the Zeeman effect would have been $(\pm 1.36), \pm 2.71$.

38. Rectifier characteristics and detection diagrams. RICHARD RUEDY, *Toronto*.—The average current I_m obtained per cycle when, in addition to the constant voltage E , the potential $E_0 \sin \omega t$ is applied to a rectifier possessing the characteristic curve $I = f(E)$, has been calculated and compared with experiment for different $f(E)$. The curve $I = ce \exp [E/e_c]$ giving at open circuit a voltage independent of E applies to all types of vacuum tubes when the A.C. voltage does not exceed a few tenths of a volt, or 0.5 volts in the case of oxide-coated emitters. The curve $I = I_0/E$ gives $I_m = I_0/(E^2 - E_0^2)^{1/2}$, and applies to certain types of glow and arc discharges in which an a.c. e.m.f. is superimposed upon d.c. Parabolic curves, for which the increase in I is independent of E , represent the actual current I_m better than the theoretical curves $I = CE^{3/2}$.

39. A new equation of state. HERBERT J. BRENNEN, *Northwestern University*.—Dieterici (Ann. d. Physik 66, 826 (1898)) put forward the equation of state: $P(V-b) = RT \exp(-A/RT)$ where P, V and T are the pressure, volume and temperature, respectively, and A, b and R are parameters. However, limit (PV/T) , as V becomes infinite, is equal to R and has the same value for one mole of all substances. Hence, we may replace RT by a new variable E and

Dieterici's equation becomes a two parameter equation. Since, a straight line intersects this equation in three real finite points at temperatures below the critical temperature, mathematical theory demands, in general, three parameters which makes Dieterici's equation, in general, mathematically absurd. Accordingly, I propose the new equation: $P(V-b) = RT \exp [-A(V-b)/RTV^n]$ which, for large values of V becomes identical with the equation (Proc. Nat. Acad. Sci. 15, 11-18, Jan. (1929)) already proposed by me, and where n is the third or missing parameter. This new equation predicts that the Law of Corresponding States is true only for substances having the same values of the critical ratio, RT_c/P_cV_c .

40. On the origin of the line absorption spectra of the rare earths. OTTO LAPORTE, *University of Michigan*.—In the rare earth group of elements the configuration $4f^n$, $4f^{n-1}5d$, $4f^{n-1}6s$ will compete in the formation of the lowest terms. For neutral atoms or ions of low order, terms with $5d$ and $6s$ electrons will be most stable; for higher ionizations, terms due to $4f$ will be lowest, as is easily seen by comparing the slopes of the Moseley curves of the three configurations in question. Consequently, there will be intermediate stages of ionization, where the Moseley lines of the $4f^n$ and $4f^{n-1}5d$ terms cross, and spark spectra, for which the frequency of the allowed transition $4f^n - 4f^{n-1}5d$ lies in the visible or at least at much longer wave-lengths than is usual for ions of (say) third or fourth order. The sharp absorption lines exhibited by rare earths in the liquid or crystal state are believed to be due to this transition. The fact that the absorption lines of gadolinium, recently measured by Freed and Spedding (Phys. Rev. 34, 945, (1929)) lie farther towards the violet than those of any other rare earth may be understood in analogy to the group-theoretical ionization potentials as obtained by Peierls (Zeits. f. Physik 55, 738, (1929)).

41. Further experiments on the disintegrative synthesis of oxygen of atomic weight 17 from nitrogen of atomic weight 14. WILLIAM D. HARKINS, *University of Chicago*, AND ARTHUR E. SCHUB, *Bell Telephone Laboratory*.—By the method of Harkins and Ryan (J. Am. Chem. Soc. 45, 2095 (1923)) approximately 34,000 photographs of alpha ray tracks from thorium C and C' were taken as they appeared in a modified Wilson-Shimizu apparatus. Two disintegrative syntheses were given by 270,000 tracks of 8.6 cm and 145,000 tracks of 4.9 cm range in air. The gas used was nitrogen. It may be assumed that the alpha-particle attaches itself to the nitrogen nucleus, thus forming the nucleus of an atom of fluorine, which in less than a millionth of a second emits a fast hydrogen particle (proton) thus giving an oxygen nucleus of mass 17. By the use of the same general procedure Blackett (Proc. Roy. Soc. A107, 349 (1925)) obtained eight, and Harkins and Shadduck (Proc. Nat. Acad. Sci. 12, 707 (1926)) obtained two such disintegrative syntheses. In this work 38 "collisions" of the alpha-particle were found in which the alpha-particle is deflected by more than 90° , while in the work of Harkins and Shadduck about 30 such collisions were found. If it is assumed that only such approximately direct impacts give a probability of a disintegrative-synthesis, then the possibility that the nitrogen thus transformed has an atomic weight of 15 seems negligible. A special search was made for the much more numerous short range hydrogen particles assumed by some workers to be emitted, but none of these were found. Thus far in this laboratory about 8 disintegrative syntheses per million long range alpha-particles, have been observed. Thus about eight protons per million long range alpha-particles were obtained in nitrogen, while Rutherford and Chadwick observed two with aluminum. However their scintillation method is not exactly comparable.

42. An isotope of nitrogen, atomic weight 15. S. M. NAUDÉ, *University of Chicago*. (Introduced by Elmer Dershem).—(The abstract of this paper appeared as a Letter to the Editor, (Phys. Rev. 34, 1498 (1929)). The following slight corrections should, however, be made in the calculated value of the wave-lengths of the isotope heads: Q_1 heads: 2155.263($N^{14}O^{17}$), 2155.753($N^{16}O^{16}$), 2156.744($N^{14}O^{18}$). P_1 heads: 2156.498($N^{14}O^{17}$), 2156.978($N^{16}O^{16}$), 2157.949($N^{16}O^{18}$). For the (0,0) band the calculated shifts of the P_1 head are for $N^{14}O^{17}$, $N^{14}O^{18}$ and $N^{16}O^{16}$, -2.595 cm^{-1} , -4.952 cm^{-1} and -3.375 cm^{-1} respectively. This corresponds to the wave-lengths 2269.536A, 2269.659A and 2269.577A.

The third from the last paragraph of the letter should read as follows: "The effect on the (0, 0) band is very difficult to observe owing to its smallness. The wave-lengths of the displaced heads found are 2269.60($N^{18}O^{16}$) and 2269.70($N^{14}O^{18}$) which correspond within experimental error with the calculated shift. The displaced head due to the $N^{14}O^{17}$ molecule could not be observed."

PROCEEDINGS
OF THE
AMERICAN PHYSICAL SOCIETY

MINUTES OF THE STANFORD MEETING, DECEMBER 7, 1929

The 160th regular meeting of the American Physical Society was held in the main lecture room of the Physics Department of Stanford University, Stanford University, California, on Saturday, December 7, 1929. There were fifty members in attendance.

There was no business of importance transacted at the meeting except the announcement by the secretary that the 164th meeting of the American Physical Society would be in affiliation with Section B of the Pacific Division of the American Association for the Advancement of Science, at the University of Oregon, Eugene, Oregon, in the period from June 18 to 21, 1930.

Papers were presented in the morning from ten until twelve-thirty, and in the afternoon from one-thirty until four-thirty. There were no papers read by title, and the relatively short program gave ample time for discussion, making the meeting a great success.

Abstracts of the 18 papers presented are given in the following pages. An Author Index will be found at the end.

L. B. LOEB, *Local Secretary for the Pacific Coast*

ABSTRACTS

1. The blue-green absorption bands of Li_2 . A. HARVEY AND F. A. JENKINS. *University of California*.—The absorption spectrum of lithium vapor contained in a nickel tube, and maintained at temperatures varying from 650°C to 900°C , has been examined under both high and low dispersion. Employing a tube 1 m long at the lower temperatures, we have identified the band heads due to the less abundant isotope molecule, Li^6Li^7 , which accompany the (1,0), (2,0) and (3,0) bands of the stronger Li^7Li^7 system. The isotope displacements agree with their calculated values within the error of measurement (calculated: 2.08, 4.32, 6.30Å; observed: 2.06, 4.47, 6.37Å. This checks the assignment of vibrational quantum numbers and the equations for the vibrational energy previously given (Phys. Rev. **34**, 1286 (1929)). Measurements of the band heads are necessarily inaccurate, because the head occurs at a low rotational quantum number. More satisfactory data may be obtained with the band lines, which are well resolved in the first order of the 15-foot grating. It has been possible to establish definitely that each band has the three-branch structure expected for a $^4\Pi \rightarrow ^1\Sigma$ transition, by using an unambiguous graphical method due to Loomis (Phys. Rev. **32**, 223 (1928)). Quantitative measurements will be made of the alternating intensities previously reported, and the rotational isotope effect in the (0,0) band investigated.

2. Why does molecular hydrogen reach equilibrium so slowly? HARVEY HALL AND J. R. OPPENHEIMER, *University of California*.—The uncatalyzed conversion ortho-para in gaseous hydrogen may be investigated quantum mechanically. A molecule of parahydrogen may be converted by collision with any other molecule to orthohydrogen; but the probability for this

conversion is small, because the conversion is induced by the very small interaction of nuclear magnetic moment with the magnetic moment of the rotating molecule. Furthermore, two molecules of parahydrogen may be converted to orthohydrogen by the interchange of nuclei between the molecules; this effect depends upon the overlapping of the wave functions for the nuclei which interchange; and its relative probability may be shown to be small, in comparison with the probability of a gas kinetic collision, of the order

$$e^{-(M/m)^{1/2}}$$

where M is the mass of the proton, and m that of the electron. The consideration of both effects shows that parahydrogen should, at N. P. T., be half converted to orthohydrogen in a period of the order of 10^8 seconds.

3. The Carbon isotope, Mass 13. A. S. KING AND R. T. BIRGE. *Mount Wilson Observatory and University of California*.—A systematic study of the carbon isotope is in progress, with the following results to date. (1) The isotope has been found in the 2-0 ($\lambda 4382$) band of C_2 , and in the 1-0 ($\lambda 3590$) band of CN, in addition to the original 1-0 band of C_2 and 0-0 band of CN. (2) Much stronger exposures of the 1-0 C_2 isotope band ($\lambda 4744$) have been obtained, in both first and second order spectra, showing at least fifteen lines suitable for measuring the isotope shift. (3) The large perturbation in line P_{33} ($\lambda 4731.8$) of the 1-0 C_2 band, does not appear in the corresponding isotope line, in agreement with theory. (4) The "staggering" in the main 1-0 C_2 band, caused by the absence of alternate rotational levels, is not present in the isotope band, again in agreement with theory. (5) The $\lambda 4744$ isotope band, as excited in the furnace, is at least ten times as strong, relative to the main band, as in the arc, where it has not as yet been observed with certainty. The relative intensity of the isotope band is thus a function of excitation conditions, and this fact may well invalidate all estimates of relative isotope abundance, based on relative spectral intensity.

4. The vibrational isotope effect. RAMOND T. BIRGE. *University of California*.—Gibson (*Zeits. f. Physik* 50, 692 (1928)) has formulated a beautiful method for calculating the vibrational isotope shift which is theoretically sound, and is the only accurate method available in the region of high values of the vibrational quantum number (n). The writer has added the details necessary for its precise numerical application, and has tested it on the absorption bands of Cl_2 previously treated by Elliott (*Proc. Roy. Soc. A123*, 629 (1929)), and of ICl , previously treated by Gibson (*loc. cit.*) and by Patkowski and Curtis (*Trans. Faraday Soc.* in press). In both these cases the theory is used to determine the correct n' numbering of the bands. The present results definitely require the half quantum numbers of the new mechanics. For Cl_2 they show that Elliott's n' numbering should be decreased by two units. For ICl they show, (1) that the main absorption progression arises from the $n''=0$ level, in apparent contradiction to a temperature experiment by Gibson (indicating the $n''=1$ level) which, however, the writer believes can be otherwise explained: (2) that Gibson's n' numbering should be decreased by one unit. Both of these latter results agree with Patkowski and Curtis' conclusions, based on a less rigorous method of calculation.

5. Equivalent temperatures in the electric arc as measured by multiplet intensities. GEORGE R. HARRISON, *Stanford University*.—It has been shown by Langmuir, Nottingham, and others, that probe measurements in the positive column of the electric arc indicate equivalent electron temperatures lying between 5000 and 70,000A, the electrons having a Maxwellian velocity distribution. Engwicht and the writer have previously shown that corrections corresponding to temperatures in the neighborhood of 8000A had to be applied to the intensities of multiplets have widely separated upper states when measured in the titanium arc under average conditions. New studies have been made of the effect of changing excitation conditions on the relative intensities of multiplets in triads, and excitation temperatures between 3000 and 15,000A have been found for the positive column of the titanium arc. The curves relating current density and electron temperature are similar to those obtained by Nottingham with the Langmuir probe for cadmium, copper, and other arcs. While probably less accurate than the probe method, the intensity method gives an excellent check on its results. The most consistent data are obtained when multiplets with common lower states are chosen, so that the most accurate self-reversal corrections can be made if required.

6. **Photographic photometry in the extreme ultra-violet.** PHILIP A. LEIGHTON AND GEORGE R. HARRISON, *Stanford University*.—The work of one of us (J.O.S.A.11, 341 (1925)) on characteristics of photographic emulsions coated with fluorescent substances when exposed to ultra-violet light has been extended to the extreme ultra-violet. Slow, medium, and fast emulsions coated with various oils have been exposed in a vacuum spectrograph under controlled conditions. Several combinations have been found which exhibit uniform contrast throughout the region 1000–3,000Å, with quite uniform sensitivity. The great difficulty of producing known variations of intensity in the extreme ultra-violet makes it desirable to find photographic materials which obey the reciprocity law accurately for use in this region. The best conditions to be fulfilled appear to be: 1. Selection of an emulsion obeying the reciprocity law accurately at wave-lengths near 4,000Å; 2. Coating it with a substance which fluoresces near this wave-length, does not absorb its own fluorescence light, and completely absorbs in a thin layer all light of wave-lengths 1,000–3,000Å. It is shown that the behavior of a given combination of emulsion and fluorescent substance in the extreme ultra-violet can often be predicted from a knowledge of the characteristics of each in the fluorescence region.

7. **The broadening of spectrum lines during early stages of spark discharges.** FRANK G. DUNNINGTON AND ERNEST O. LAWRENCE. *University of California*.—The voltage across a spark gap drops to a relatively small value in 10^{-8} sec. after the beginning of the discharge. The cross-section of the discharge during periods of the magnitude of 10^{-7} sec. after breakdown, however, has not been observed, but there is evidence that it is small and therefore that the discharge current density is enormous. Such large initial ionic densities should be evidenced by large Stark effect broadening of spectrum lines in the early stages of sparks. Using the Beams electro-optical shutter we have photographed the light emitted by sparks during 5×10^{-7} sec. after breakdown. As expected all spectrum lines are diffuse, the spark doublets ($3d_{1,2}-4f$) of Mg, ($3d_1-4f_1$, ($3d_2-4f_2$) of Cd and Zn for example, having a breadth of approximately 40Å. From existing data on the Stark effect of Mg it is calculated that the average ionic field producing the here observed Stark effect broadening is about 600,000 volts/cm, and that approximately 1/2 of the molecules in the path of the discharge are ionized. The luminosity of the metallic vapor was observed to spread from the cathode at a velocity of 1.2×10^{-8} cm/sec.

8. **The effective collision cross-section of cadmium and zinc atoms for slow electrons.** ROBERT B. BRODE. *University of California*.—The variation with the electron velocity of the effective collision cross-section or the absorption coefficient, α , has been measured in the vapors of cadmium and zinc and found to follow a curve of the type previously found for mercury. (Proc. Roy. Soc. 125, 134, (1929)). The cadmium curve has a maximum at about 40 volts, $\alpha = 130$, and a minimum at about 25 volts, $\alpha = 126$, followed by a steady rise with decreasing velocity to the limit of accurate measurements, 1 volt, $\alpha = 700$. The zinc curve has a very flat maximum at about 50 volts, $\alpha = 76$, a minimum at about 36 volts, $\alpha = 74$, followed by a steady rise to $\alpha = 500$ at 1 volt. As in mercury vapor a very small change in the general slope is observable in both of the curves just beyond the first resonance potential. The magnitude of the maximums are in the order ; Cd, $\alpha = 125$; Zn, $\alpha = 75$ and Hg, $\alpha = 60$. Other related properties of these atoms such as the molar refractivity and the critical potentials show this same irregularity in order.

9. **A direct measurement of molecular velocities.** I. F. ZARTMAN, *University of California*.—The molecules whose velocities are to be measured are vaporized in an electrically heated crucible. A sharply defined molecular beam is formed by two rectangular slits, one of which is placed in the cover of the crucible, the other 3.8 cm above the crucible slit. A steel cylinder, 9.41 cm inside diameter, which is rotated by an electric motor has a slit in its periphery and supports a glass collecting plate (which has been coated with a thin uniform deposit of the substance to be investigated) on the inner face diametrically opposite the slit. The entire assembly is operated in a vacuum of less than 10^{-4} mm and at speeds varying between 120 and 240 r.p.s. The molecules in the group entering the cylinder possess a distribution of velocities. These molecules pass to the opposite side of the cylinder and are collected on the glass plate in the form of a velocity spectrum whose density is measured with a microphotometer. The

velocity v of the molecules $= \pi d^2 n / s$ where d = diameter of the cylinder, n = r. p. s., and s = displacement of the molecules. Three runs taken with Bi at 800°C indicate that it vaporizes as a monatomic molecule. The displacement corresponding to the most probable speed in the beam at 120 r. p. s. is 0.7 cm. Other substances are now being investigated.

10. Experiments on the reported fine structure of the molybdenum K_β lines. SAMUEL K. ALLISON AND J. H. WILLIAMS. *University of California*.—Davis and Purks (Proc. Nat. Acad. Sci. 14, 172, (1928)) have investigated the K-spectrum of molybdenum with a double x-ray spectrometer and obtained a complete resolution of the K_β doublet with both crystals reflecting in the second order. They report a new line $K_{\beta'}$, 24 seconds of arc (0.17 X.U.) on the long wave-length side of K_{β_1} . The intensity of this new line appears to be about 1/3 that of K_{β_1} . An attempt has been made to study this new line using a double spectrometer with both crystals in the second order, and one in the second and one in the third order. Experiments were carried out at 42.7 kv and 45.6 kv. No positive evidence could be obtained for a satellite of K_{β_1} in the reported position. From the curves obtained it appears that if such a satellite is present at the voltages stated above, its intensity must be less than 1/10 that of K_{β_1} . An average of eight determinations of the wave-length separation of β_1 and β_2 gives $\Delta\lambda = 0.572 \pm 0.003$ X.U. Previous values obtained with the single spectrometer were 0.563 X.U. (Allison and Armstrong, Phys. Rev. 26, 701, (1925)) and 0.565 X.U. (Larsson, Phil. Mag. 3, 1136, (1927)).

11. The electric space charge in the lower atmosphere. JOSEPH G. BROWN. *Stanford University*.—During the past year continuous records of space charge have been obtained 7.5 meters above the earth's surface. Obolensky's method of gathering all the ions from a known volume of air and measuring the residual charge has been used. The mean value of the positive charge has been about 0.10 E. S. U. per cubic meter. This value lies between Obolensky's and Kahler's. The air was quite free from dust which gives large negative charges, or smoke which gives large positive charges. If the air is still the space charge is remarkably constant, but if in motion sudden changes occur. This fact has led to the conclusion that most variations at a given point are due to different bodies of air which have different charges. At night when the air becomes saturated the positive space charge decreases and negative charge often occurs. During rain large positive or negative charge results. The mean diurnal variation is almost the reciprocal of the temperature variation, though there is a decided tendency to agree with the potential gradient. Sudden changes in space charge are accompanied by corresponding changes in potential gradient, though many changes in potential gradient are not accompanied by changes in space charge.

12. Variation of the electric potential gradient in the lower atmosphere. JOSEPH G. BROWN. *Stanford University*.—The mean electric field is characterized by a negative surface charge and a positive space charge. The mean distribution of the positive space charge can be inferred from the values of the potential gradient at different elevations, since $d^2 V / dh^2 = -4\pi\rho$. Approximate computation shows that 50 percent of the charge is in the first kilometer, 18 percent in the second, etc., Variations in mean distribution will cause variations in potential gradient at any point by changing the relative magnitudes of the space charges (a) in horizontal layers and (b) in vertical columns. Expansions and convection currents will produce such changes in distribution and hence determine potential gradients. Continuous records of potential gradient and space charge have been obtained for a year 7.5 meters above the surface and their diurnal variations compared with the diurnal system of convection as inferred from the meteorological elements. In general upward currents near the surface correspond with increased charge and potential gradient, while downward correspond with decreased. General expansion and overflow above correspond with decreased charge and potential gradient, while cooling and inflow above correspond with increased. This is in agreement with the theory. Dust, smoke, and condensation are important factors but are believed to be of secondary importance in determining the mean diurnal variation.

13. **The multiple crystal x-ray spectrograph.** JESSE DUMOND AND HARRY KIRKPATRICK, *California Institute of Technology*.—An x-ray spectrograph designed to obtain increased intensity and contrast in spectra of scattered x-rays has been designed and built. The instrument consists of fifty small units each containing a Seeman wedge and calcite crystal. The units are closely spaced on the arc of a circle of one-half meter radius and are oriented with great precision so that the spectra from the different units are exactly superposed. The spectra are photographed on a film bent to conform to an arc of the same circle. The geometry of the instrument is such that when the crystals are oriented so as exactly to superpose one spectral line from all of them, all wave-lengths and all orders are exactly in superposition. The instrument can take two forms having respectively a virtual point source and a real point source. The form having the virtual point source is the one here described. Beside the gain in intensity and contrast the instrument permits the study of scattered radiation over a wide range of scattering angles with almost perfect homogeneity of scattering angle.

14. **Adjustments and tests of the multiple crystal x-ray spectrograph.** HARRY KIRKPATRICK AND JESSE DUMOND, *California Institute of Technology*.—The technique of adjusting the crystals of the multiple crystal x-ray spectrograph is described and some improvements in design are suggested. Preliminary results obtained from a setting of seventeen of the crystals show that very good resolution is possible. The lines have a breadth of less than half an X.U. the dispersion being about 0.2 mm per X.U. The lines resulting from the superposition of seventeen crystals are not appreciably broader than the lines from one crystal and are seventeen times as intense showing that the superposition is practically complete. A preliminary test using the instrument to investigate the Compton effect for Mo K radiation scattered at 90 degrees from a paraffine scatterer with extremely homogeneous scattering angle confirms the result obtained by one of the authors for 180 degrees scattering that the so-called Compton line is diffuse. According to the work of Bergen Davis a fine line structure may be superposed on this broad diffuse structure though no theory has been yet given to account for such fine lines in the Compton shifted position. Attempts are being made to locate these lines with the multiple crystal spectrograph.

15. **Photographs of single crystals of ice, grown from the vapor.** JOHN MEAD ADAMS, *University of California at Los Angeles*.—The abstract of this paper appears as a Letter to the Editor in this issue, p. 113.

16. **Valence electrons in the diamond.** M. L. HUGGINS AND RUTH PARRISH, *Stanford University*.—Previous calculations of density of scattering power for x-rays by means of Fourier series have involved the assumption that the structure can be resolved into two face-centered cubic structures, with the atoms oriented in the same way in both, and with three mutually perpendicular planes of symmetry passing through each atomic center. By taking the origin at a center of symmetry, midway between two atoms, this doubtful assumption need not be made. The resulting curves of density of scattering power show a small peak midway between each two neighboring carbon atoms. These peaks may be due to the electron pairs constituting the valence bonds.

17. **A method of calculating complex spectra.** WILLIAM V. HOUSTON, *California Institute of Technology*.—It is possible to build up, in a step by step process, the proper functions to represent any spectral term in the zero approximation. The coefficients occurring in these functions can be determined once for all by solving a set of simple simultaneous equations. From these functions, it is easy to compute the first approximation to the energy levels by integration over radial functions and spherical harmonics. If the radial integrals are not carried out, the integrals over the spherical harmonics still suffice to determine a number of relationships between the energies of the various multiplets. The accuracy of the determination is best when there are no other electron configurations with nearly the same energy as the one under consideration. The step by step process of setting up the functions gives at once the correlation between atomic terms and the ionic terms with which they are associated. It is then possible to apply the electron spins as a further perturbation. This leads to a determination of relationships between interval ratios in a multiplet and the interval ratios between multiplets.

18. The mobilities of gaseous ions in Cl_2 and Cl_2 -air mixtures. LEONARD B. LOEB, *University of California*.—Work of the early investigators and of Herbert Mayer indicates that the presence of traces of Cl_2 reduces the mobility of the negative ion below that of the positive ion, a fact which appeared inconsistent with a theory of Condon and Loeb. No other investigations of mobilities of *both* ions in pure Cl_2 had been undertaken. The possibility that the discrepancy between theory and observation in earlier work was caused by HCl made a more careful investigation imperative. Cl_2 carefully prepared by heating CuCl_2 and free from both HCl and H_2O was used. It was found that the values of the mobilities in pure Cl_2 on the new absolute standard for positive and negative ions was 0.654 and 0.510 cm/sec per volt/cm respectively. A study of mixtures of dry air and Cl_2 showed that traces of Cl_2 less than 0.1 percent reduce the negative mobility below that of the positive ion. The positive mobilities were little affected by the presence of Cl_2 , so that positive ions obey Blanc's law in Cl_2 -air mixtures, indicating the absence of disturbances due to dipole moments in Cl_2 as is to be expected. The behavior of the negative ion shows a clustering effect of considerable magnitude which has no simple electrochemical explanation.

PROBABILITY AND CRITICAL POTENTIALS FOR THE FORMATION OF MULTIPLY CHARGED IONS IN HG VAPOR BY ELECTRON IMPACT

BY WALKER BLEAKNEY

PHYSICAL LABORATORY, UNIVERSITY OF MINNESOTA

(Received December 15, 1929).

ABSTRACT

With a type of apparatus previously reported the procedure is described for measuring the probability of the formation of multiply charged ions in mercury vapor as a function of the velocity of the incident electron.

Critical potentials for the formation of multiply charged ions. New results together with those of an earlier paper place the minimum or ionizing potentials for the formation of Hg^+ , Hg^{2+} , Hg^{3+} , H^{4+} , and Hg^{5+} by a single impact at 10.4, 30, 71, 143, and 225 volts respectively. A brief correlation of these results with those of other observers is given.

Relative numbers of multiply charged ions. A set of curves is given showing the fraction of the total positive ion current carried by each type of ion as a function of the electron velocity. Another set of curves shows the fraction of the total number of ions carrying one, two, three, four, and five charges. The fraction for Hg^+ drops to a nearly constant value of 78 percent while the value for Hg^{2+} approaches 16 percent of the total number beyond 150 volts. At 400 volts the values for the five ions in order are 77, 16.5, 4.4, 1.3 and 0.8 percent respectively.

Quantitative measure of the number of ions produced and effective cross-sectional area of the Hg atom. Curves are given representing the number, N , of each type of ion, per electron, per cm path, per mm pressure at 0°C as a function of the electron velocity. The values of N for Hg^+ , Hg^{2+} , Hg^{3+} , and Hg^{4+} have maxima of 20.8, 3.2, 0.72, 0.15 at 50, 115, 210, and 400 volts respectively. The effective cross-sectional area of the Hg atom toward an ionizing collision of a given type is obtained by dividing the appropriate value of N by the number of molecules per cc. The maximum value of this area for Hg^+ is about 60 percent of the kinetic theory value.

A discussion is given of the meaning of the area under the peaks in the e/m analysis curves and its effect on the accuracy of the interpretation of the data.

I. INTRODUCTION

BEFORE our knowledge of the probability of ionization in gases by electron impact can be complete it is necessary to investigate the critical potentials for the formation of multiply charged ions, and the effective cross-sectional area of the molecule or atom toward an ionizing collision as a function of the energy of the incident electron. Heretofore the types of apparatus used by investigators in this field have been such that the total number of unit positive charges was observed and not the actual number of ions formed since

an ion may carry several positive charges. It is important, therefore, to study separately the probability of the formation of ions having one, two, three, or more charges. Until recently no direct experimental method had been devised capable of such an investigation. The success of any method requires that only the primary products be examined, that is, the pressure of the gas must be such that there is little chance of an electron colliding twice and the current density of electrons must be so low that there is also little chance of an ion being struck a second time. The scheme proposed in a recent paper¹ lends itself very well to work of this kind. As yet a study has been made of mercury vapor only. A preliminary report² of some of the results has already been made.

II. APPARATUS AND PROCEDURE

The apparatus used in the present experiment has already been described¹ in considerable detail and the reader is referred to this paper for the principles and details of the design. A plan view is shown in Figs. 1 and 2 for convenience in the discussions which follow.

Fig. 1. Side view of apparatus.

Fig. 2. End view.

The pressure of the mercury vapor was controlled by regulating the temperature of a trap in the exhaust line containing liquid mercury. The data for the pressure of the vapor corresponding to the temperatures used were taken from the International Critical Tables. The best temperature at which to work was found to be in the neighborhood of -20°C or a pressure of 1.81×10^{-5} mm Hg. Temperatures in this region were maintained either by a mixture of NaCl and ice or by solid CCl_4 . The latter melts at -24°C . The temperature of the ionization chamber was measured by means of a thermocouple and was always found to be about 45°C . Since the mean free path of the atoms was much greater than the diameter of the connecting tube a pressure correction for diffusion was made to get the true pressure in the tube.

The electron current required in most cases was about 3×10^{-7} amperes. It was measured by means of a galvanometer of 4,000 megohms sensitivity. A potential (usually about 90 volts) was applied to the plate P positive with respect to the surrounding box of a magnitude sufficient to give a saturation current. The galvanometer measured the current to the box and plate com-

¹ W. Bleakney, Phys. Rev. **34**, 157 (1929).

² W. Bleakney, Phys. Rev. **35**, 123 (1930).

bined, thus obviating any correction due to ions being formed inside the box. It is believed that secondary electrons escaping from this arrangement were quite negligible. The positive ion current arriving at the plate *B* was measured with a Leeds and Northrup galvanometer of 110,000 megohms sensitivity. Saturation current to this plate was observed with a field V_2 as low as 0.3 volts per cm. The field strength used for the final runs was 3.3 volts per cm. The current to the plate *K* was measured with a Compton electrometer at a sensitivity of 2000 mm per volt. For the larger currents a direct deflection was observed by shunting the instrument with India ink resistances. For very small currents the time required to deflect through a given distance on the scale was measured.

Fig. 3. A typical e/m analysis curve. $V_1 = 350$ volts. $p = 1.8 \times 10^{-6}$ mm Hg.

A set of preliminary runs was taken at various values of the field V_2 . It was found that the relative sizes of the peaks remained unchanged between 1.2 and 3.5 volts per cm. A second set of preliminary runs was taken at various pressures, the results showing that the effects of scattering and neutralization were negligible at the pressures finally used. The final set of runs was then taken at electron velocities ranging from 20 to 500 volts.

III. RESULTS

In Fig. 3 is shown a curve typical of a large number obtained with the apparatus. The electrometer current is plotted as a function of the crossed field E . In this instance the accelerating potential for the electrons V_1 was set at 350 volts, the drawing out field V_2 at 3.3 volts per cm, and the pressure was that corresponding to saturated mercury vapor at -20°C or 1.8×10^{-6} mm

Hg. The magnetic field furnished by the solenoid amounted to 400 gauss. The curve distinctly reveals the five mercury ions Hg^+ , Hg^{2+} , Hg^{3+} , Hg^{4+} , and Hg^{5+} . Only one impurity shows up to any extent and its ionization potential was found to be 14.5 volts. It seems certain then that it is a singly charged ion and its position indicates a molecular weight of 28. These two facts are strong evidence for its being a CO^+ ion.

Fig. 4. A series of e/m analysis curves taken at various electron velocities.

Figure 4 illustrates a series of curves taken at electron velocities ranging from 35 to 350 volts. The ordinates of the different curves have been reduced to correspond to the same pressure and the same electron current throughout.

Critical potentials for the formation of multiply charged ions at single impact. If the areas under the peaks are plotted as a function of the electron velocity and the curves extrapolated to zero area the minimum or critical potentials for the formation of the different ions at a single collision are obtained. These

values may be called the ionization potentials for single impact. To the four values reported in the first paper¹ there is now added a fifth. The curves are shown in Fig. 5. The ionization potential for Hg^{5+} was difficult to determine with any accuracy because of the proximity of the Hg^{4+} peak and a very

Fig. 5. Curves showing the ionization potentials at single impact.

slight impurity which coincided with the Hg^{5+} peak. Assuming the value of Hg^+ to be 10.4 volts the values, with the estimated probable errors, of Hg^{2+} , Hg^{3+} , Hg^{4+} , and Hg^{5+} are placed at 30 ± 1 , 71 ± 2 , 143 ± 3 , and 225 ± 5 volts respectively. There has been observed only slight evidence for the Hg^{6+} ion while Hg^{7+} and Hg^{8+} , if any are formed, are completely masked by the CO^+ impurity.

Fig. 6. Percent of total current carried by each type of ion.

Relative numbers of multiply charged ions. It will be assumed that the area under each peak of the e/m analysis curves is proportional to the current due to that particular type of ion and the validity of this assumption will be examined later. The curves of Fig. 6 representing the fractions of the total

current due to the different ions are obtained by plotting the area under each peak divided by the total area as a function of the electron velocity. Between 10.4 and 30 volts the positive ion current is 100 percent singly charged, and the effect of the appearance of the other ions is to lower this value to a nearly

Fig. 7. Percent of total number of ions having one, two, three, four and five charges.

Fig. 8. Total number of positive charges, N^+ , per electron per cm path per mm pressure at 0°C. constant one of 59 percent at the higher velocities. The fractions of the total current due to Hg^{2+} and Hg^{3+} reach maximum values of 27 and 11 percent respectively.

To find the relative abundance of the different ions in *number* it is necessary to consider the total area under the first peak, one half the area under the

second, one third the area under the third, and so forth, as fractions of the sum. The curves of Fig. 7 show the results of this calculation. The ordinates for the fourth and fifth ions are here multiplied by 10. It will be noticed, for instance, that while at 300 volts the current due to Hg^+ is only 60 percent of the total yet 78 percent of the ions actually formed are singly charged.

Quantitative measure of the number of ions and the effective cross-sectional area of the Hg atom. As has been stated before the total number of positive charges arriving at the plate *B* was measured. Let the number of positive charges formed per electron per cm path per mm pressure at 0°C be denoted by N^+ .

The values of N^+ are indicated in Fig. 8 as a function of the electron velocity. The curves of two other observers are shown for comparison. Curve I,

Fig. 9. Number of Hg^+ , Hg^{2+} , Hg^{3+} , Hg^{4+} , and Hg^{5+} ions per electron per cm path per mm pressure at 0°C and effective cross-sectional area of the Hg atom.

reduced to 0°C , is from the work of Compton and Van Voorhis.³ Curve II, corrected to conform to the pressure and temperature data used in this article, is taken from the paper by T. J. Jones.⁴ Curve III was obtained by the author and was used in the calculations which follow. Curves II and III agree fairly well as indeed they should since they were obtained by the use of the same type of apparatus. The maximum in the curve found in the present experiment has a magnitude of 25.2 at 75 volts compared to 24.6 at 90 volts as observed by Jones. Beyond the maximum the results of Jones are consistently higher than curve III. At present an attempt is being made in this laboratory with a new apparatus to measure the quantity N^+ with greater accuracy. If such a determination should prove different from the results here given the following results may be easily revised to conform to the new data.

³ K. T. Compton and C. C. Van Voorhis; Phys. Rev. **26**, 436 (1925) and **27**, 724 (1926).

⁴ T. J. Jones, Phys. Rev. **29**, 822 (1927).

Having measured the total number of positive charges and the fraction due to each type of ion it is possible to calculate the actual number of each type by taking values from the curves of Fig. 6, multiplying by the corresponding N^+ from Fig. 8 and dividing by the number of charges on the ion. These results have been plotted in Fig. 9 where N is the number of ions per electron per cm path per mm pressure at 0°C as a function of the electron velocity. The ordinates for the last three ions have been multiplied by 10. Now if the number N be divided by the number of atoms per cc the quotient is the effective cross-sectional area of the Hg atom toward an ionizing collision. This area is indicated by the scale on the right margin of Fig. 9. The kinetic theory value for this area is in the neighborhood of $10 \times 10^{-16} \text{ cm}^2$ depending on one's choice of the recorded values for the diameter of the mercury atom. Although the total positive ion current exhibits a maximum at an electron velocity of about 75 volts yet when the ions are examined separately the maximum yield for Hg^+ occurs at 50 volts. Maxima for Hg^{2+} , Hg^{3+} and Hg^{4+} appear at 115, 210, and 400 volts respectively.

IV. DISCUSSION

Because of its complicated structure there has been no theoretical treatment worked out to predict the ionization potentials in mercury vapor. Of course the first, 10.4 volts, is well known from a host of critical potential experiments. The determination by Lawrence⁵ is probably the most accurate, and his value agrees with spectroscopic measurements. Smyth,⁶ using a method of positive ray analysis, found doubly charged ions appearing at 19 volts while Carroll,⁷ from an analysis of the spectrum of Hg II, gets the same value. These values represent the energy necessary to remove the second electron after the first is gone. If the energy required to remove the first is included they are in satisfactory agreement with the value given by the present investigation.

It was assumed, earlier, that the area under any peak in the e/m analysis curve was proportional to the current due to that type of ion. Suppose the ions are traveling in the x direction and the slit has a width dy . Then for any particular setting of the field E the electrometer measures the number of ions which fall between y and $y+dy$ a quantity which is equivalent to dn/dy where n is the total number of charges between y_0 and y . This is the quantity which is plotted as a function of E , and measuring the area under the curve is equivalent to performing the integration,

$$\int_{E_0}^{E_1} (dn/dy) dE$$

a quantity which has dimensions different from that which we wish to find. The integral which we would like to find is

$$\int_{E_0}^{E_1} (dn/dy)(dy/dE) dE$$

⁵ E. O. Lawrence, Phys. Rev. **28**, 947 (1926).

⁶ H. D. Smyth, Proc. Roy. Soc. **A102**, 283 (1922).

⁷ J. A. Carroll, Phil. Trans. Roy. Soc. **A225**, 365 (1925).

and only in case dy/dE is equal to a constant is the area as measured proportional to the current. The analytical expression for dy/dE can be found from the equations of motion but it is not simple and it involves the unknown initial velocity distributions of the ions. The numerical value therefore can only be roughly approximated. It was thought, therefore, that an experimental attack might prove more fruitful.

Professor Tate pointed out that if the factor by which the area under a peak must be multiplied to get the current is the same for all the peaks then this factor is equal to the total current entering the analyzing chamber divided by the total area under the curve. It was decided, therefore, to measure the current and area at various electron velocities to see if the ratio remained constant when different peaks were involved. The current issuing from the first slit was measured with the high sensitivity galvanometer while the electrometer measured the current through the second slit in the usual way. The experimental error of such a determination is rather large because of the low intensity of the current to the galvanometer. Ten runs were made with electron velocities ranging from 20 to 70 volts. Below 30 volts only the single ion is formed while below 70 volts only single and double ions may exist. In these runs the ratio of current to area showed a maximum deviation of 3 percent from the mean and displayed, moreover, no systematic variation with increasing numbers of doubly charged ions. Tests at higher electron velocities gave similar results although the experimental error was greater. The conclusion is that the area is proportional to the current within the experimental error of this test. It should be pointed out, however, that the experimental error for the determination of the ratio for the second peak alone is perhaps ten or twelve percent since it contains at most only about one fourth of the total area. In general the smaller the peak the less certain are the measurements.

Another test was made by connecting the galvanometer to the plate *C* Fig. 2, and measuring the current arriving at this plate as a function of the field *E*. With $E=0$ all the positive ions issuing from the lower slit fell upon *C*. As *E* was increased a point was reached at which singly charged ions were prevented from reaching the plate and the remainder was measured by the galvanometer. Here, also, the accuracy is not great because the separation of the ions is not precise at the current densities required, but the results agreed substantially with the previous test.

The original data as represented by the curves in Fig. 4 can be reproduced quite accurately. It is in the interpretation that great care must be exercised lest errors creep in. It is believed that the results as represented by the curves in Figs. 5 and 6 are very close to the true values.

The calculation of the probability of formation of the different types of ions is dependent on the measurements of the total ionization and different observers are somewhat at variance on these values. The results obtained in the present work are in fair agreement with those of Jones, and Compton and Van Voorhis (see Fig. 8) but are not at all in agreement with those of von

Hippel.⁸ It is argued by him that a crossed field due to contact potentials swept out the multiply charged ions before they were measured and hence his results apply to Hg^+ only. Even so, the author cannot correlate von Hippel's data with the present work, and it appears that his theory that the maximum yield occurs at twice the ionization potential is untenable.

Smyth,⁶ who was the first to investigate the multiply charged ions in mercury vapor by means of a mass spectrograph, states that at the higher velocities the number of doubly charged ions is nearly equal to the number singly charged. From the appearance of his curves it is probable that it is the *current* which is nearly equal in the two cases. If this be true then both Jones and von Hippel have misinterpreted Smyth's data.

It seems to be quite generally assumed that the classical kinetic theory value for the mean free path of an electron is $4(2)^{1/2}$ times the mean free path of an atom of the gas. This value has apparently been used by Hughes and Klein,⁹ Compton and Van Voorhis,³ Jones,⁴ and others in their calculations. It seems to the author that this is not the true kinetic theory value for high speed electrons such as were used in all of these experiments, the more appropriate value being

$$\lambda = 1/\pi r^2 N$$

where N is the number of atoms per cc and πr^2 is the kinetic theory value of the cross-sectional area of an atom. The difference in the two points of view is very marked in the case of mercury. The maximum effective cross-sectional area of a mercury atom toward an ionizing collision of the first type calculated on the basis of the latter argument is at least 60 percent of the kinetic theory value, while Jones, and Compton and Van Voorhis on the basis of their calculations get a little over 30 percent for any type of ion. It is interesting to note in the curves of Compton and Van Voorhis that mercury vapor gives the largest yield of positive charges of any gas used and it is among the lowest in probability of being ionized and yet the kinetic theory value for the size of the mercury atom does not differ greatly from the others.

The author has been unable to check the calculations for curve 2, Fig. 3, in the paper by Jones⁴ and it is believed that this curve is in error. It also seems that a correction for diffusion due to the large difference in temperature between trap and tube should have been made in the pressure before calculating the values for curve 1 of this same figure.

It is essential to point out that while the number of Hg^+ ions, for instance, has been measured yet what electron was removed in its formation is unknown. This fact makes a theoretical explanation of the observed phenomena even more difficult.

Work on hydrogen and the rare gases has been started and it is hoped that these results may be reported in the near future.

Many thanks are due Professor John T. Tate for his ever present interest and timely suggestions in the prosecution of this problem.

EXPERIMENTS ON THE REPORTED FINE STRUCTURE AND THE WAVE-LENGTH SEPARATION OF THE $K\beta$ DOUBLET IN THE MOLYBDENUM X-RAY SPECTRUM

BY SAMUEL K. ALLISON AND JOHN H. WILLIAMS
UNIVERSITY OF CALIFORNIA, BERKELEY

(Received November 26, 1929)

ABSTRACT

A nomenclature is suggested for describing the possible positions of the double x-ray spectrometer. A position may be defined by (n_A, n_B) where n_A is the order of reflection on crystal A ; n_B the order on B . n_A is to be considered always positive. n_B is negative if the position of crystal B for the reflection of a wave-length incident upon it is such that by turning B through an angle of less than 90° the reflecting surface of B can be made parallel to that of A , and the given wave-length be reflected in this parallel position. If this convention be adopted it is shown that general equations for the instrument may be easily set up. Experiments on the separation of the $K\beta_1$ doublet of molybdenum at the position (2, 2) at 43-46 kv and 22 m.a. show that if the line $K\beta'$ reported by Davis and Purks¹ exists, its intensity is less than 1/10 that of β_1 at these voltages. An average of eight determinations of $\Delta\lambda$ for MoK, β_1, β_2 gives 0.572 ± 0.003 XU.

SUMMARY OF PREVIOUS WORK

THE doublet character of the $K\beta_1$ line in x-ray spectra has been noted by various experimenters.¹ Allison and Armstrong obtained a considerable separation of the doublet for molybdenum in the 5th order of a single crystal ionization spectrometer, and found $\Delta\lambda = 0.563$ XU. The intensity ratio β_1/β_2 was found to be 2/1. Larsson achieved a separation of the doublet photographically and found $\Delta\lambda = 0.565$ XU. Kellström investigated the doublet in the second order and obtained good separations in palladium and silver, and a very good separation was obtained by Enger and photometered, for the case of rhodium. Davis and Purks, using a double spectrometer, obtained a complete separation of the doublet with both crystals reflecting in the second order. They report a new line $K\beta'$, 0.172 XU. (24 seconds of arc at the dispersion used) to the long wave-length side of $K\beta_1$, and of intensity about 1/3 to 1/2 that of β_1 . The voltage at which their tube was operated was not stated in their report. The photographs taken

by Enger in rhodium were obtained at 50–60 kv and no such line is indicated on them. An attempt has been made to study this new line in molybdenum, using a double x-ray spectrometer.

APPARATUS

Several standard molybdenum target tubes supplied by the General Electric Co. for crystal analysis work were used in the course of the experiments. These tubes were cooled by a pump circulating kerosene through the hollow target; the kerosene after entering and leaving the target through insulated glass tubes, was cooled by passing through a copper spiral immersed in running water. The target and the cathode of the tube were at potentials above and below ground respectively. The focal spot was at a distance of 53 cm from crystal *A*, and the radiation used was taken off at an angle of 8° with the target face. A description of the double spectrometer used has been previously published.² The horizontal angular width of the beam (angular width in a plane perpendicular to the axes of rotation of the crystals) was determined by the width of the slits of the instrument, which were 35 cm apart. These slits were 1.5 and 1.8 mm wide in various experiments. The voltmeter which measured the voltage across the x-ray tube was connected between the cathode side of the tube and ground, and therefore measured only half the total potential drop across the tube. It was found by trial that the potential of the anode above ground was very nearly equal to that of the cathode below ground so that the indication of the voltmeter needed only to be multiplied by two. The tube current in all experiments was 22 m.a., the voltage in some was 43 kv and in some 46 kv. In the course of the experiments three different sets of calcite crystals were used.

NOMENCLATURE FOR THE DOUBLE X-RAY SPECTROMETER

Since two crystals are used in the double x-ray spectrometer, we have found it convenient to specify their positions by giving two numbers n_A and n_B which represent the orders in which crystals *A* and *B* are reflecting respectively. The corresponding glancing angles are θ_A and θ_B . The sign of n_A is to be taken as positive in all cases. The sign of n_B is determined as follows. If the position for crystal *B* for the reflection of a given wave-length incident upon it is such that by turning *B* through an angle less than 90° the reflecting surface of *B* can be made parallel to that of *A*, and the given wave-length reflected in this parallel position, n_B is negative. If an angle greater than 90° must be traversed in order to bring the crystals to this type of parallel position, n_B is positive. According to this convention, so-called "parallel position_{act}" (Ehrenberg and Mark³ Case I; Schwarzschild⁴ Case II) are special cases of a number of positions in which n_B is to be considered negative. Using this convention, we may write for the dispersion *D*,

² Williams and Allison, J.O.S.A. & R.S.I. 18, 473 (1929).

³ Ehrenberg and Mark, Zeits. f. Physik 42, 807 (1927).

⁴ Schwarzschild, Phys. Rev. 32, 162 (1928).

$$D \equiv \frac{d\theta_B}{d\lambda} = \frac{n_A}{2d \cos \theta_A} + \frac{n_B}{2d \cos \theta_B} \quad (1)$$

in which $d\theta_B$ is the angular range on crystal B corresponding to the wave-length range $d\lambda$, and d is the grating space (assumed to be the same on both crystals).

If the absolute value of n_B is greater than that of n_A and n_B is negative, D is negative, and the sense of rotation of crystal B to pass from shorter to longer wave-lengths is the reverse of that for cases in which D is positive. This is the case, for example, in the position $n_A = 1$, $n_B = -2$, which we designate as the $(1, -2)$ position. Here the dispersion is negative, and for molybdenum K radiation its magnitude is only slightly greater than that from a single crystal reflecting in the first order.

Using the conventions suggested here, Schwarzschild's equation⁵ for the "geometric breadth" $\delta\theta_B$, in the case in which the two axes of rotation lie in the reflecting faces of the crystals and are parallel, may be written

$$\delta\theta_B = \frac{1}{2} D \lambda \phi^2. \quad (2)$$

In the preceding equation, $\delta\theta_B$ is the angular range through which crystal B may be turned while reflecting the wave-length λ . D is the dispersion defined by (1). ϕ is one-half of the maximum angle between any two rays incident on crystal A in a plane parallel to the axis of rotation of A . In other words, if the only restraint upon the divergence of the x-ray beam is that it must pass through two equal rectangular apertures separated by a distance L , whose height, or dimension in a plane parallel to the axis of rotation of the crystal is h , then $\phi = h/L$.

If the geometric width $\delta\theta_B$ has been made small in comparison to the observed width, and can be neglected, the following equation holds for the width observed for any line in the spectrum at any position of the crystals:

$$W = (W_A^2 + W_B^2 + D^2 W_\lambda^2)^{1/2}. \quad (3)$$

In this equation W represents the half width at half maximum in angular measure of the observed "rocking curve," W_A the half width at half maximum in angular measure of the curve (assumed Gaussian error curve) representing the intensity of reflection from crystal A as a function of the deviations from the Bragg angle, W_B is the analogous quantity for crystal B , D is defined in (1) and W_λ is the half width at half maximum of the line in question in linear measure.

ATTEMPT TO FIND THE LINE $K\beta'$

Some of the curves we have taken which have the most direct bearing on the intensity of the line $K\beta'$ are shown in Fig. 1. These curves were all

⁵ Schwarzschild expressed this equation in the form $\delta\theta_B = 1/2(\tan \theta_1 \pm \tan \theta_2)\phi^2$ in which the negative sign was to be chosen when the crystals are in a position where "the first incident and the last reflected rays are on opposite sides of the first reflected ray." This agrees with our method of designating the sign of n_B .

taken in the (2, 2) position (both crystals in the second order, reflecting faces not parallel).

Curve (a). This curve was taken at 43 kilovolts and 22 milliamperes. The rate of deflection of the electrometer observed on a scale 225 cm from the instrument was 0.744 mm per second at the highest point of $K\beta_1$. At the base-line point on the short wave-length side it was 0.163 mm per second. The voltage sensitivity of the electrometer on the scale at this distance was 4.5 meters per volt. The capacity of the insulated system was not accurately known but was of the order of magnitude of 10^2 cm. The width of the lines

Fig. 1. Typical curves bearing on the intensity of $K\beta'$.

to be expected from geometric sources may be calculated from Eq. (2). The vertical adjustment of the two crystal faces was made by observing the reflection of a beam of light from their faces. This beam was made horizontal by passing through two narrow slits held on a cathetometer and was very nearly perpendicular to the reflecting crystal surfaces. The crystal was then tilted about a horizontal axis until the reflected beam was in the same horizontal plane as the incident beam. This adjustment was accurate to 2 minutes of arc. ϕ was calculated from the height of the focal spot (3 mm) and the height of crystal B (18 mm) and the distance from the target of the tube to crystal B (71 cm). This gives $\phi = 0.0147$, $\delta\theta_B = 9.5$ seconds of arc. The half width at half maximum of the curve for β_1 is approximately 15.5 seconds of arc; the preceding calculation shows that this cannot be explained as due to geometrical causes only. We do not wish to take up the question of the width of x-ray lines here, leaving this for a later publication. The half

width at half maximum of the curve at $(1, -1)$ for these crystals was 3.1 seconds of arc.

Curve (b). This curve was taken with the same arrangement as that of curve (a) except that a vertical stop 7.5 mm high was introduced at a distance of 48 cm from the target. This gives $\delta\theta_B = 5.2$ seconds of arc from Eq. (2). The voltage was 43 kv. The rate of deflection of the electrometer (scale and sensitivity as for curve (a)) at the highest point on the peak was 0.398 mm per second; at the lowest point shown on the short wave-length side it was 0.093 mm per second. The half width of the peak at half maximum is about 14 seconds. An accident to the x-ray tube prevented continuing the curve to cover β_3 .

Curve (c). This curve was taken on a different set of crystals and with a different target from that used in curves (a) and (b). The voltage was 46 kv. The rate of deflection of the electrometer (same arrangement as for (a) and (b)) at the highest point of β_1 was 0.475 mm per second; at the lowest point on the short wave-length it was 0.162 mm per second. The value of ϕ and consequently of $\delta\theta_B$ was the same as that for curve (a). For various unknown reasons the curve (c) is less reliable (as indicated by the scattering of the points) than curves (a) and (b). The half width at half maximum of the curve at $(2, -2)$ for the crystals used was 1.5 seconds of arc.

The vertical arrows in Fig. 1 show the angular positions at which β' should appear (24 seconds of arc to the long wave-length side of β_1) according to the results of Davis and Purks.¹ In curves (a) and (b) the total intensity here is about 1/5 of that at the maximum. In these curves, the vertical dotted line represents the center of the line $K\beta_1$; the horizontal dotted line its width at an angular distance of $24''$ from the center. It is evident that within the accuracy of the readings the curve is symmetrical in this region about an ordinate through its maximum. We can therefore obtain no positive evidence for the presence of the line $K\beta'$ at the voltage used.

A rough estimate of the maximum possible intensity in the form of the line $K\beta'$ which could be present in our curves may be obtained by assuming a Gaussian error curve for β' symmetrical about the position indicated, and of the same half width as that for β_1 . The distortion of the symmetry of β_1 which would be thus produced can be plotted by adding up the contributions from β_1 and the supposed β' at various abscissae. Proceeding by this method the conclusion was reached that the curves (a) and (b) could not have failed to show evidence of a line in the specified position of intensity 1/10 that of β_1 . Our conclusion is therefore that there is no line at this position of intensity greater than 1/10 that of β_1 under the conditions of the experiment.

DETERMINATION OF THE WAVE-LENGTH SEPARATION OF THE DOUBLET $K\beta_1, \beta_3$ IN MOLYBDENUM

In the course of the investigation many curves have been taken of the doublet in question in various positions of the double spectrometer. Eight of the most reliable of these have been selected for the purpose of obtaining an accurate value of $\Delta\lambda$ for this doublet. The results are shown in Table I.

TABLE I. Observations on the wave-length separation of β_1, β_3 .

Position n_A	n_B	Dispersion from Eq. (1)	$d\theta_B$ obs.	Av. $d\theta_B$	$\Delta\lambda$ calc.	Weight
1	1	68.46"/XU	39.1"	39.1"	0.5711XU	2
1	2	103.8	61.0 61.2 59.5	60.6	.5835	9
1	3	140.7	80.0	80.0	.5687	4
2	2	139.2	78.5 77.0	77.8	.5587	8
2	3	176.0	101.5	101.5	.5766	5

The weights assigned in the last column of Table I are the products of the number of observations for a given position by $(n_A + n_B)$ for that position, since it was supposed that higher dispersion gave more accurate results. The weighted mean of the measurements shown in Table I is

$$\Delta\lambda = 0.572 \pm 0.003 \text{ XU}$$

in which the probable error has been computed according to the usual methods.⁶ This value is slightly higher than the values 0.563 XU observed by Allison and Armstrong¹ and 0.565 XU observed by Larsson.¹ In general the effect of greater resolution of a close doublet should be to increase the estimate of its wave-length separation. The errors in the value quoted must be mainly due to two factors (1) the uncertainty of the electrometer readings, and (2) the fact that a change of temperature of the crystals might have taken place between the time of reading one peak and the time for the next.

THE INTENSITY MAXIMA IN THE CONTINUOUS
HELIUM SPECTRUM

BY JANE M. DEWEY

EASTMAN LABORATORY, UNIVERSITY OF ROCHESTER

(Received December 9, 1929)

ABSTRACT

The position of the maxima of the continuous spectrum of helium was measured with an arc in which measurements of ion concentration was made. The displacement of the maxima to the red by stray fields in the gas was calculated from the formula $E = -2e(eF)^{1/2}$ given by Robertson and Dewey and more recently by Kudar. The observed displacement is always larger than the calculated. Reasons for this are discussed.

IN A paper in this journal¹ H. P. Robertson and the author suggested an explanation of the displacement of the maxima of continuous atomic spectra to the red of the limit of the spectral series. It was assumed that the effect is due to the stray fields set up in the gas by the ions and free electrons, and the least energy for which aperiodic orbits are possible was calculated from the complete formula for the Stark effect on the basis of the classical quantum theory. Kudar² has recently obtained the same value for this limit of the continuous spectrum from general reasoning on the basis of the quantum mechanics. It is not possible to carry through the calculation in quantum mechanics as the complete equation is not soluble and is known to give no discrete states unless some restriction is imposed. Since the quantum mechanics must go over into ordinary mechanics for large quantum numbers, or atomic states of energy close to zero, the classical mechanics should give the correct formula for the displacement of the spectral limit. The uncertainty which it introduces lies rather in the fact that it gives no information as to the relative probabilities of the various transitions which are possible.

EXPERIMENTAL PROCEDURE

The spectrum of a hot cathode helium arc very similar to that described in an earlier paper³ was photographed, with a Hilger E3 quartz spectrograph, and the position of the maximum intensity in the continuous spectra determined with a recording microphotometer. The cathode of the arc was a cylinder of platinum foil, coated with barium oxide and heated by a current put through it lengthwise. A Langmuir exploring electrode used to measure the electron concentration was placed in the center of the cylinder with its axis perpendicular to the axis of the cylinder. One photograph on which the intensity of the continuous spectra could be measured was obtained with a

Schüler tube containing a similar electrode. Even when the exploring electrode was small (1 mm of seven mil wire) the discharge tended to avoid its neighborhood, as could be seen by visual observation of the tube. This was probably due to recombination of the ions on the glass insulation of the electrode and to the cooling effect of the electrode. As the curves from which the electron temperatures and concentrations were obtained were regular and obtained without difficulty, the removal of electrons by the electrode itself cannot have caused a serious disturbance. The most serious difficulty in the measurement of ion concentration was that it sometimes caused a sudden increase in the current which melted the glass insulation from the electrode. The ion concentration which could be obtained in the tube was limited by the heating effect.

Helium was chosen rather than an alkali metal to avoid the possibility of the atomic spectrum being complicated by unresolved bands or continuous molecular spectra. The helium recombination spectra have been observed by Paschen⁴ and more recently by Mohler and Boeckner.⁵ For purposes of photometric measurement they have the serious disadvantage of being accompanied by bands. Mohler and Boeckner report that the bands are greatly reduced in intensity by the addition of a trace of mercury to the helium but in the discharges used in this investigation this did not appear to be the case. It was not found possible to eliminate the bands in any way except by the reduction of both pressure and ion concentration, which also reduced the intensity of the recombination spectra. The arc was more suitable than the Schüler tube as the bands were strong only when a high current was put through the arc. The tube used by Mohler⁶ and by Mohler and Boeckner apparently would give better spectra but has the disadvantage that the ion concentration must be measured by an indirect method. Probably the bands were weakened on the one plate taken with a Schüler tube on which the intensity of the continuous spectra could be measured by some impurity accidentally present. This was the first plate taken with a newly set up Schüler tube and all subsequent exposures showed very strong bands. The difficulty of estimating the intensity of the continuous spectrum when bands appear on the plate can be seen on the excellent reproductions which accompany Paschen's paper. The bands are strongest in the neighborhood of the $2p$ limit but the weak bands in the ultra-violet also make measurements on the $2s$ limit difficult. The small dispersion of the spectrograph used made measurements at the $2p$ limit of parhelium impossible. The range of ion concentrations included in these results is small and the estimated fields uncertain but, as it was necessary to discontinue the investigation, it seemed worthwhile reporting such results as were obtained.

Table I gives the results. The field is calculated from the formula of Holtsmark,⁷ taking account of the presence of both ions and electrons by doubling

is given. From the formula $E = -2e(eF)^{1/2}$ the calculated displacement is obtained, where F is the field and e the charge on the electron.

DISCUSSION

The displacement of the limit observed is in every case larger than that calculated. This is to be expected from the serious error in the electron concentrations introduced by the avoidance of the neighborhood of the exploring electrode by the discharge. Since the intensity of the continuous spectrum increases as the square of the electron concentration the spectrum observed will be essentially the spectrum of the region of the discharge in which the concentration is highest. All other sources of error, both in measurement and in calculation, will probably result in discrepancies in the same direction, but it is probable that this error is so large as to mask all others. One source of error in the calculation may be large. Oppenheimer⁸ has pointed out that there is a possibility of dissociation, and therefore of recombination on the basis of the new mechanics even when the energies of the ions and electrons do not permit it according to classical mechanics. The general argument that the results of the two types of mechanics must approach each other for large quantum number makes it improbable that this introduces serious error, although it is conceivable that it might. It is not possible to estimate the magnitude of the effect from Oppenheimer's or Kudar's formulae as for the upper excited states of the atom the change in energy due to the field is as large as the total energy of the states even for small fields and cannot be calculated from perturbation theory.

A more complete study of the effect would be desirable, accompanied if possible by a determination of the field in the source by an independent method, such as the intensity of forbidden lines appearing in its spectrum, as it appears to give a reasonably direct method of estimating the ion concentrations in stellar sources.

These measurements were made in Palmer Physical Laboratory, Princeton University, while the author was a fellow of the National Research Council. She is greatly indebted to Dr. K. T. Compton for his interest in the work as well as for extending to her the privilege of working in the laboratory.

SCHOTTKY EFFECT AND CONTACT POTENTIAL
MEASUREMENTS ON THORIATED
TUNGSTEN FILAMENTS

BY NEIL B. REYNOLDS

PALMER PHYSICAL LABORATORY, PRINCETON UNIVERSITY

(Received December 7, 1929)

ABSTRACT

The Schottky effect for thoriated tungsten filaments is investigated and Schottky's relation that $\log i \propto (V)^{1/2}$ is verified at high fields, but fails at gradients below 10000 volts/cm, even for fully activated surfaces. This lack of saturation at low fields is accentuated by the effect of bombardment with high velocity positive ions, such bombardment apparently producing a surface roughening and consequently increased fields in local areas. Investigation with low accelerating and retarding voltages, while varying the temperature and state of activation of the filament, allows a comparison of the contact potential and the work function at the absolute zero of temperature (ϕ_0) for the thoriated surface. The two values (contact potential and ϕ_0) are found to vary with a one-to-one correspondence if ϕ , the work function at the temperature of measurement, be allowed a temperature coefficient. This coefficient is much larger than can be attributed to the specific heat of the electrons in the metal. The electrons with high velocities show a Maxwellian velocity distribution. Near the zero of potential there are certain anomalous effects and a "patch surface" is postulated which, in a qualitative manner, explains this behavior and the lack of current saturation with voltage gradients below a limiting value.

SCHOTTKY,¹ many years ago, derived an equation to explain the increase of saturation thermionic current with anode voltage. This relation has been verified by many investigators for pure metallic electron emitters, especially in the last few years. With one or two exceptions, the analogous effect with composite cathodes has been neglected, and the present paper deals with the current-voltage relations for thoriated tungsten filaments over a range of anode potentials from retarding potentials of 10 volts to accelerating potentials of 5000 volts, corresponding to potential gradients of nearly 500000 volts/cm.

A number of tubes were used in these experiments, varying slightly in detail but of the same general design. A 1.6 mil thoriated tungsten filament was stretched in the center of a cylindrical nickel or molybdenum anode. This was constructed in three pieces, on the guard ring principle. An alkaline earth metal was vaporized on the wall of the tube as a getter. The tube was given the best possible exhaust, baked, the metal parts degassed, and then sealed off from the pumping system. The tube was so designed that it could be completely immersed in liquid air.

The temperature of the filament was determined from the watts input according to the latest temperature scale of Jones.² Since all three parts of the

anode were maintained at the same potential but currents were measured only to the center cylinder, the effects of filament cooling at the leads and of field distortion at the edges were eliminated. Currents were measured by galvanometers and a Rawson multimeter, with a system of shunts giving a measuring range from 1 ampere to 5×10^{-11} amperes. Batteries, a 1500 volt dc generator and a 20000 volt full wave rectifier gave a complete range of anode potentials.

Langmuir and others³ have described the methods of manipulation of thoriated tungsten cathodes. In these experiments the state of activation of the filament was controlled by allowing thorium to diffuse to the surface at lower temperatures, or by raising the temperature and removing it by evaporation. It is practically impossible to obtain a completely deactivated thoriated filament even by flashing at very high temperatures since diffusion occurs while the filament is cooling. In the present instance it was possible to obtain values of θ as low as 0.30 (θ = fraction of the surface covered).

Becker⁴ has distinguished between the amount of barium present on a tungsten filament and the amount effective in lowering the work function. Since in the experiments reported in the present paper the emission obtained from the filament was used as the criterion of θ according to Langmuir's relation that $\log i \propto \theta$, there is no contradiction and θ might more properly be defined as the fraction of the tungsten covered with thorium atoms which are effective in lowering the work function.

Becker and Mueller⁵ reported that partially activated thoriated and caesiated tungsten surfaces obeyed Schottky's relation,

$$\log i = \log i_0 + \frac{K}{T} \left(\frac{dV}{dx} \right)^{1/2}$$

at high electric fields, but deviated from this as zero potential was approached. They discussed the nature of the fields to be expected close to non-homogeneous surfaces and concluded that poor saturation was to be expected from partially activated cathodes. This effect has been known for some time, but as a subject of detailed study it has been neglected. Dushman⁶ and others in their calculations of the electron emission from composite surfaces have projected the $\log i$ vs. $(F)^{1/2}$ line from high fields to zero potential and assumed this as the current emitted at zero field. Since this extrapolated value was several times greater than the current actually obtained, some doubt was thrown on the procedure and it was thought important to investigate in detail the relation between electron current and anode voltage so as to obtain some sort of an explanation of the departures at low fields and perhaps a work-

age about 10 percent higher than the calculated. Table I gives results for various runs at different temperatures and values of θ .

The position of the critical field V_1 must next be considered. This varied slightly from run to run, and the discussion of the effect of positive ion bombardment will show one reason for this variation. However, under the best vacuum conditions, the point of departure from the straight line was constant at about 10000 volts/cm. This appeared to be a limiting minimum value, independent of the temperature and of the state of activation of the filament. So, between $\theta=0.30$ and $\theta=1.0$, and between $T=1100^\circ\text{K}$ and $T=1600^\circ\text{K}$, Schottky's relation held with very fair accuracy for fields greater than 10000 volts/cm, and this limiting value was characteristic only of the surface thorium on tungsten.

It is interesting to note that in Becker and Mueller's paper, Fig. 5 shows the curve approximating to a Schottky straight line at high voltages but departing from it at about 15000 volts/cm, which is in fair agreement with the results obtained here.

The portion of the curves between V_1 and V_0 , the zero of applied potential, presents something of a puzzle. The results vary a great deal, but averaging a large number of runs and eliminating possible complicating factors, there seems to be a certain amount of regularity. Curves *A* and *B* of Fig. 1 illustrate this. It will be noted that curve *A* approaches the dotted straight line more gradually than does curve *B*. These are two runs at the same temperature, where $\theta_A > \theta_B$. This example and numerous others lead to the generalization that the point of departure, V_1 , is approximately independent of θ , but as θ is decreased, the curve falls away more and more steeply. So far, attempts exactly to analyze this portion of the data have failed, yielding only this observed qualitative result.

Removal of liquid air from around the tube resulted in the liberation of small amounts of gas. Thoriated tungsten surfaces are very sensitive indicators of the presence of the least traces of even chemically inert gases, since positive ions produced by electron impacts are accelerated to the filament and remove thorium, reducing θ and consequently the emission obtainable at a given temperature. With "residual gas" ions, this effect becomes important at around 40–50 volts. After such *low voltage bombardment*, the general nature of the $\log i$ vs. $(V)^{1/2}$ curves was unchanged, but was shifted vertically downward due to the decrease in the emission current. However, if *bombardment at 400 volts or higher* was maintained for a considerable period of time (15–60 minutes), subsequent $\log i$ vs. $(V)^{1/2}$ curves in good vacuum exhibited marked changes.

Figure 2 illustrates this. Curve *A* is a normally activated filament. Curve *B* was taken after positive ion bombardment at 400 volts. The filament was then flashed at 2800°K and reactivated and curve *C* taken. This last has been shifted downward in the figure for purposes of spacing. Actually the upper parts of *B* and *C* practically coincide, while at low voltages the currents of *C* are considerably higher than those of *B*.

The effect of bombardment was a semi-permanent one. Subsequent activation and deactivation by temperature (below 2700°) shifted the curve along the current axis but did not otherwise alter its unique character. Flashing at

2700°K or higher, where rapid sintering of tungsten is known to take place, destroyed the effect of bombardment and subsequent activation produced normal $\log i$ vs. $(V)^{1/2}$ curves.

When gas was present in the tube and a run was made, first with ascending and then descending voltages, bombardment occurred while readings were being taken and the curve would not retrace its original path. When the maximum potential used was 1000 volts or higher, the return curve was actually higher than the ascending one, but broke away sooner and crossed the first. A second ascending curve retraced the previous descending one, returning still higher and giving a second sort of hysteresis loop. Thus a filament which at low fields gave higher emission currents than a bombarded one which

Fig. 2. Curves illustrating effect of positive ion bombardment at 400 volts. Curve A, normally activated filament; B, after bombardment; C, after reactivation. Curve C is shifted downward from practical coincidence with A.

had less thorium present, actually produced less current than the bombarded filament when fields of the order of hundreds of thousands of volts per centimeter were applied. The indication was that something other than the amount of thorium present determined the emission.

A study of the diffusion characteristics of the bombarded filament throws some light on this behavior. Subsequent to severe bombardment, diffusion of thorium to the surface of the wire from the interior occurred at temperatures much lower than in normal thoriated tungsten filaments. The activation rate at 1800°K was about that expected in a normal wire at 2100°K. It is known that diffusion of thorium in tungsten occurs most readily in fine grain structures, presumably along the crystal boundaries. An explanation suggests itself, that the effect of the bombarding positive ions may have been to rup-

ture the surface of the tungsten, producing a superficial fine crystal structure which facilitated the diffusion of thorium atoms. If this had also produced some sub-microscopic roughening, there would have been points where the field strength would have been greatly increased. This would account for a more rapid increase of the current with applied voltage, and an apparent, but not an actual deviation from Schottky's relation.

It was not possible during the course of this investigation to repeat these experiments with a pure tungsten filament and verify this hypothesis, free from the complicating influence of the thorium. However, Bartlett⁷ has reported similar results with pure tungsten, giving curves resembling those shown here. He reported difficulty in eliminating gas, and stated that his procedure was to flash the filament and then bombard his anode to red heat to remove gas. Only after this process was he able to obtain satisfactory results. He had only 1000 volts available and was able to go only to about 60000 volts/cm. Up to this point his curves were steeper than the theoretical Schottky line, but were rounding over and approaching this slope. His degassing schedule was an ideal one to produce positive ion bombardment of his filament. It seems possible that the lack of saturation he reports may be the same phenomenon noted here—a roughening of the surface by a positive ion “sand blast”—and that if he had continued to higher fields the curves might have straightened out along the conventional Schottky line. The highest fields used by Bartlett are of about the same order of magnitude as the point of departure of the bombarded curves in the present investigation.

II. LOW AND RETARDING POTENTIALS

If the electrons emitted from a filament at a given temperature all had zero or a constant initial velocity normal to the emitting surface, at a certain anode potential the current should rise abruptly from zero to its full value, and then remain constant, subject to the increase predicted by Schottky's equation, as the potential is increased. It has been shown by several investigators⁸ that the emitted electrons have an initial velocity distribution given by Maxwell's equation (via Schottky)

$$i = i_0 \frac{2}{\pi^{1/2}} \left[\left(\frac{Ve}{KT} \right)^{1/2} e^{-Ve/KT} + \int_{(Ve/KT)^{1/2}}^{\infty} e^{-x^2} dx \right].$$

Thus, if complicating effects such as voltage drop along the cathode be eliminated, the current should break at a definite potential, and as the anode is made more negative the current should fall away so as to make the $\log i$ vs V plot substantially a straight line. The sharp break point defines the absolute zero of potential, i.e., the state at which the anode and cathode are at the same potential, and the difference of this from the zero of applied voltage gives the contact difference of potential (CDP) between the anode and cathode materials. Comparison of two different cathodes or states of surface of the

⁷ R. S. Bartlett, Proc. Roy. Soc. A121, 456 (1928).

cathode with the same anode provides a method of determining changes in the contact potential of a material.

This method was used in examining thoriated tungsten filaments with accelerating and retarding fields in the neighborhood of zero field. Figure 3 shows a typical curve. It will be noted that the left hand portion of the curve follows a straight line, and that after passing through the transition region near zero, the points again approach the nearly straight line saturation value. It was decided to consider the intersection of these two lines, as the experimentally determined zero of potential as a basis for the determination of contact potential differences. This is designated in Fig. 3 as V_c . A justification of this will be given in the discussion to follow.

Fig. 3. Typical curve for determining contact potentials.

That part of the straight line just to the left of V_c is a theoretical, not an experimentally obtained curve, since the plotted curve falls away from it before V_c is reached. One cause of this deviation is the voltage drop along the filament cathode. The length of the center anode cylinder of the tube was 2.8 cm, and the difference in the cathode potential opposite the upper and lower ends was considerable and varied with the filament temperature. For this, a first order correction was applied. This was accomplished by first determining the potential of the mid-point of the filament. Then since the current from the most negative end was greater than from the most positive end, and the contribution of each element of the filament did not vary linearly along the filament, a method of graphical integration was used to determine what may be designated as the potential of the effective mid-point of the filament. This is the potential, which applied to a unipotential cathode would give the same observed current. The correction showed that only a part of the devia-

tion near zero could be attributed to the effect of filament drop since, whereas the correction was effective over only a few tenths of a volt range, the observed deviation extended over a range of one or more volts on either side of the determined zero. The effect of the correction on the retarded straight portion of the curve was simply to produce a small lateral shift, altering the actual value of the contact potential break but not the slope of the $(\log i)/V$ line.

Taking this corrected point as zero, and calculating from the filament temperature the fraction of the corresponding saturation current having different initial velocities, a series of points was obtained from Maxwell's distribution law coinciding with the corrected experimental line within the limits of experimental error. Over a 500°C temperature range this effect was verified. At least those electrons with high initial velocities had a Maxwellian velocity distribution. It will be shown later that the apparent deviation of the low velocity electrons (those contributing to the curve near zero voltage) from this distribution was not an actual deviation but was the result of quite another phenomenon.

The low electronic work function of a composite surface, such as thorium on tungsten, has generally been attributed to the effect of the contact difference of potential existing between the thorium and tungsten atoms at their point of contact.⁹ Whether the electrons come from the tungsten and are aided in their escape by local fields due to the thorium film, or whether they come from the thorium atoms themselves, it is impossible to state with certainty. Since the currents obtained from the thoriated tungsten are slightly greater than those from a pure thorium filament at the same temperature, and some tens of thousands of times greater than from pure tungsten, it seems reasonable to assume that the emission is that from thorium, modified by the proximity of the tungsten base.

Dushman's¹⁰ derivation of the thermionic emission equation leads to the result:

$$i_0 = AT^2 e^{-b_0/T}$$

where $b_0 = (e\phi_0/K)$, or $\phi_0 = (K/e b_0)$, and ϕ_0 is the work function of the surface at the absolute zero of temperature. From this equation, it is seen that the value of ϕ_0 for any condition of cathode surface can be found from the slope of the line obtained by plotting $(\log i - 2 \log T)$ against $1/T$. This value of ϕ_0 varies with the amount of thorium present on the surface, ranging from 4.5 volts ($b_0 = 52400$) for pure tungsten, to 2.6 volts ($b_0 = 30500$) for a completely activated filament.

In a preceding paragraph it was pointed out that the difference of the abscissa coordinate V_c from the zero of applied potential V_0 gave a measure of the contact difference of potential between cathode and anode materials. By measuring this difference for different values of θ , to each of which corresponded a definite value of ϕ_0 obtained as just described, a relation was arrived

at connecting the change in contact potential with the change in ϕ_0 for a range of surface conditions. Measurements of the C.D.P. were also made over as wide a range of temperatures as the measuring instruments and other limiting conditions allowed. Since the C.D.P. should be related to ϕ , the work function at the temperature of measurement, while ϕ_0 should be a constant independent of temperature, and presumably

$$\phi = \phi_0 + \pi(T),$$

a study of the change of the C.D.P. with temperature should give an insight into the nature of the function $\pi(T)$. Results are tabulated in Table II.

Column III gives the value of ϕ_0 for different values of θ as obtained from the emission data. Column IV lists the contact potential differences from the measurements with retarding fields. These are denoted by π_θ , since they represent results for varying values of θ . Let ϕ_1 denote the value of ϕ_0 for $\theta = 1$ and ϕ_θ for any given value of θ ; π_1 and π_θ the corresponding C.D.P. values. Then it is assumed that $\Delta\pi_\theta = \pi_\theta - \pi_1 = \Delta\phi_\theta = \phi_\theta - \phi_1$. Hence $\pi_1 = \pi_\theta - \Delta\phi_\theta$.

Thus, from the observed values of π_θ , an averaged plot of π_1 was obtained as a function of the temperature. These values of π_1 are given in column V. This smoothed curve was used to give corrected values of π_θ , from the observed $\Delta\phi_\theta$. Column VI shows these corrected results, for comparison with the originally observed values of C.D.P. (π_θ). The best justification for this process is the agreement between columns IV and VI. The last two columns give the actual and percentage deviations of IV and VI. In VIII, those cases have been omitted for which the values of $(\pi_\theta - \Delta\phi_\theta)$ were of the order of magnitude of the probable errors of measurement.

In most cases in the experiments, the measurements with retarding fields were made at 0.05 volt intervals throughout the critical range. However, due to the approximation in the correction for filament drop, no claim is made to an accuracy of better than 0.1 volt. The actual magnitude of the measured C.D.P. between the filament and nickel anode can have very little significance. The nickel was at all times positive to the filament. It was noted that after long operation it was impossible to reproduce the earlier readings, an effect traceable to evaporation of thorium to the anode and a consequent shift in the potential of the nickel surface.

The foregoing calculations were based on the assumption that $\Delta\phi_0 = \Delta\pi_0$, and the reasonably close agreement resulting seems to justify this assumption. This seems to be a direct experimental support of Richardson's theory of the essential identity of contact difference of potential and difference of work functions. From this viewpoint, the data of column V are of considerable qualitative interest. They may be interpreted as giving the temperature coefficient of ϕ .

Previous investigators have failed to show conclusively that the work function changes with the temperature. Germer¹¹ obtained what appeared to be evidence for such a change, but later attributed it to temperature effects inherent in the anode. Whatever the effect in pure metals—tungsten, platinum, and the like—it is small, and the conclusion reached is that the electrons which produce the thermionic current do not share in the temperature equilibrium in the metal. If they did have a share in the specific heat of the solid they should, by the equipartition theory, contribute an amount at most of the order of $2kT$, an effect barely detectable in these experiments. The results obtained here indicate a temperature coefficient of ϕ of the order of 2×10^{-3} volts per degree, or in the neighborhood of $20kT$. To attribute this to degrees of freedom is obviously absurd.

The constancy of ϕ_0 in the emission equation is not to be doubted, and the method by which the work function is here determined precludes obtaining the value of ϕ and analyzing it for temperature dependence. DuBridge¹² has pointed out that since, for composite surfaces, A in the equation is not constant, and ϕ_0 is by definition a constant, any temperature coefficient of ϕ will be concealed in A . No effort has been made as yet to study the mutual dependence of A and ϕ in a quantitative way.

III. THEORETICAL TREATMENT

Langmuir and also Richardson and Young¹³ have considered a patch surface to account for lack of saturation of electronic and photoelectric currents from thin electropositive films. Becker and Mueller¹⁴, in their paper on thoriated and caesiated filaments, calculated that at non-homogeneous surfaces the fields between the two types of atoms should produce the observed depar-

¹⁴ Becker and Mueller, Reference 5.

tures from Schottky's plot at low applied fields. While any concrete representation of phenomena of atomic behavior may be questioned, the following considerations apparently do offer a tentative explanation of the effects set forth in the foregoing sections of this paper. These considerations were suggested by Dr. K. T. Compton in discussing the interpretation of the present work. It was learned later that the same idea had been carried to a partial quantitative stage a number of years ago by Langmuir and Mott-Smith, but not published.

The work function of a surface is the work required to remove an electron from the surface to infinity. The Thomson method of images furnishes a way of calculating this work, which can be expressed to a first approximation as

$$\phi = - \int_0^{\infty} (e^2/4x^2) dx.$$

But this leads to an infinite value for ϕ . This difficulty is overcome by assuming that within some small distance x_0 some other law applies, while beyond it the relation given above holds good. Langmuir¹⁵ has shown that whether the force between the surface and x_0 be assumed to be constant or to increase parabolically from zero, the result is the same and the work to reach x_0 is $W = e^2/4x_0$ and then

$$\phi = \frac{e^2}{4x_0} + \frac{e^2}{4x_0} = \frac{e^2}{2x_0}.$$

A simple calculation will show that the work required to remove an electron to a distance $10 x_0$ is 19/20 that needed to remove it to infinity. Thus the factors operating in this region close to the surface are the ones most effective in modifying the work function of the metal and the emission of electrons.

For a perfectly smooth, homogeneous surface, the electric field is constant at any distance outside it, and the work function is constant over it. If, instead of the surface being homogeneous, it consisted of single, isolated atoms of one metal distributed regularly over the surface of the foundation metal, the electric field at atomic distances would be disturbed by the effect of the contact potential between the two metals. However, at a distance of several atomic diameters the field would be very nearly uniform and consequently ϕ would be nearly constant for the whole surface.

The third possible distribution capable of any sort of study would consist of patches of the electropositive material distributed at random over the surface of the other. If such a patch consisted of many hundreds of atoms, it would appear to an electron at a distance $10 x_0$ normally out from the center of the patch as an infinite plane, and the field acting on the electron, and consequently the work function as applied to that electron would be a perfectly definite magnitude, characteristic of the patch material. Between the patch and the basic metal there would be a potential difference equal to the

¹⁵ Langmuir, Trans. Am. Electrochem. Soc. 29, 125 (1916).

C.D.P. between the two metals. Let Fig. 4-I represent such a surface. The shaded portions are patches of thorium and the adjacent areas tungsten.

Between these two there is a potential difference of about two volts (assumed since ϕ_0 for full activation is 2.6 volts and for clean tungsten is 4.5 volts). There will be lines of force originating on the thorium, as shown on the diagram. The effect of the fields of force will be to aid electrons to escape from the tungsten but to hinder their escape from the thorium. Since we assume the electrons under consideration to come exclusively from the thorium, the first effect can be ignored. The retarding action will be more pronounced near the edge of the thorium areas, falling off rapidly as we move toward the center of the patch, and becoming fairly constant and negligible over the central portion.

Fig. 4.

Let the dotted line of Curve II-Fig. 4 represent the field resulting from the C.P.D. between thorium and tungsten. The exact shape of the field distribution is indeterminate, but the one shown should be approximately correct. Assume for the present the electrons all to have zero initial velocities. If an external field E_a be applied, the combined effect of this and the "patch field" will be that of the solid line (Fig. 4-II). The shaded area represents the portion of the field accelerating electrons away from the surface. The length defined by it along the abscissa axis represents the part of the thorium covered surface from which electrons can escape from the surface under the influence of the applied field E_a . As E_a is increased from zero, emission begins as soon as the heavy solid line appears above the E_0 axis. Since the center portion of this curve is shown as flat, the area from which electrons can escape increases first rapidly with the voltage, then more and more slowly until finally the whole of the resultant field is in the direction to accelerate electrons away from the metal. At this point, the whole area of the thorium patch is an effective emitter, and the applied field is just strong enough to overcome the maximum field between thorium and tungsten at the point of contact of the two areas. This critical field is independent of the fraction of the surface covered with thorium so long as there remain exposed lines of contact of the two metals.

It should be characteristic only of the C.D.P. between the two metals concerned, and should vary for different pairs of elements.

If now the electrons be assumed to have a Maxwellian distribution of velocities, characteristic of the temperature, investigation with retarding fields should show a perfectly normal distribution curve for the portion BAB' and since we have assumed this line nearly flat, falling off sharply at B and B' , the distorting effect of the patch field should be a minimum. As zero is approached and the shoulder of the curve BC begins to emit, the Maxwellian curve will be distorted by the increasing effective area of the thorium brought into action.

Application of this analysis to the typical curve of Fig. 3 shows agreement of the postulated theory and the experimental result throughout the length of the curve. Retarding fields show a Maxwellian distribution. In the neighborhood of zero potential a saturation current is reached, modified by the neutralization of the patch field by the applied field and by the Schottky effect. The patch effect is less and less important with increasing fields until at the point V_1 (Fig. 1) the whole patch area emits and above this there is saturation emission, increased by the Schottky correction. It will be evident that for some distance above V_1 Schottky's relation will apply only approximately, as the field effective in reducing the surface work function is the difference between the field applied and the field due to the proximity of the tungsten, which is non-uniform over the area of the thorium patch. At very high applied voltages, where the patch field becomes negligible, Schottky's equation should represent the results with very satisfactory accuracy.

The choice of the point V_c as the zero of potential in the contact potential curve (Fig. 3) may need some justification. The point D , lying as it does on the actual curve, would seem at least an equally appropriate reference point, since only *changes* in contact potential are involved. However, the accuracy with which it can be determined is much less. Moreover, this point is modified by the velocity distribution of electrons and is therefore dependent on the temperature. Its sharpness of definition depends upon the shape of the shoulder of the curve E_R (Fig. 4-II). The extrapolated intersection at V_c is much less open to these objections. Also, due to the steepness of the slope of the portion CD (Fig. 3) and the flatness of AV , the uncertainty in the line AV due to its actual curvature introduces only a slight error in the determination of the hypothetical zero of potential at V_c .

It is important to note that the necessity of assuming a patch field even for a fully activated surface leads to the conclusion that the tungsten is never fully covered, but that there exist a maximum number of thorium areas distributed over the surface. If the break at V_1 (Fig. 1) is a constant for thorium on tungsten and this field is equal to the maximum retarding field exerted on electrons at the edge of the thorium areas by the tungsten atoms, this field should be of the order of magnitude of the C.D.P. (circa 2 volts) divided by some length which is of the same magnitude as that of the patches. For any different combination of elements, this critical field V_1 should have a different constant value. Thus for caesium on tungsten it should be larger, presumably in proportion to the larger contact difference in potential.

On the basis of this theory there seems to be a real significance to Dushman's extrapolation of the Schottky line to zero field to obtain i_0 . This represents the emission from the actual area of electropositive metal present, free from the effects of both the "patch field" and the applied field, and is characteristic of the work function of the surface under consideration.

I take pleasure in acknowledging my indebtedness to the Charles A. Coffin Foundation, since most of the present investigation was carried out while holding one of its Fellowships at Princeton University. Also I tender sincere thanks to Professor K. T. Compton, under whose direction this research was conducted, and whose contributions were many and invaluable; to Dr. S. Dushman, of the General Electric Research Laboratories, for suggestions and criticism; to others in the Laboratories of that company for assistance in preparing apparatus; and to Mr. Robert W. Graves for aid and collaboration during part of the work.

Note added with proof: Since sending this paper to the publisher, these results have been discussed with Dr. Langmuir who has extended his calculations on the properties of a patch surface and reaches conclusions which are in complete disagreement with the observed facts on the Schottky effect. The explanation of this inconsistency between the theoretical deductions and the observations is to be included in a joint report in preparation by Dr. Langmuir and Professor Compton to be published in a forthcoming number of the Physical Review Supplement.

THE TEMPERATURE DEPENDENCE
OF FIELD CURRENTS

BY NORMAN A. DE BRUYNE*

TRINITY COLLEGE, CAMBRIDGE, ENGLAND

(Received November 12, 1929)

ABSTRACT

The increase in the field current observed by Millikan and Eyring to take place at about 1000°K is shown to be of the order of magnitude of the thermionic emission to be expected from a thoriated filament at this temperature. The author considers that the results of Millikan and Lauritsen are inconclusive and do not definitely establish the existence of a dependence of field currents upon temperature. The author has carried out new experiments using an improved method of investigation and has been unable to detect any temperature variation in the field current. His contention is not that no temperature variation exists but that no real variation has yet been observed.

ALL investigators¹ are agreed that from 80°K to 1000°K the auto-electronic, or field, emission is independent of temperature. There is however a difference of opinion about the existence of a temperature dependence above 1000°K . Millikan and Eyring² observed an increase in the emission at this temperature but, by separating out the thermionic from the field current in a mixed emission, I found³ that the field current showed no systematic increase with temperature and therefore concluded that the increase observed by Millikan and Eyring was due to the occurrence of a thermionic emission. Millikan and Lauritsen⁴ have recently stated that the increase in emission observed by Millikan and Eyring "is about a billion times too large to be so interpreted;" this statement is evidently based on the emission characteristics of pure tungsten and disregards the fact that Millikan and Eyring used thoriated filaments. The thermionic emission from a thoriated tungsten filament is in fact of the order of magnitude of the increase observed by Millikan and Eyring, as may be seen from the following considerations.

THE RESULTS OF MILLIKAN AND EYRING

The diameter of the filament used by Millikan and Eyring was 0.00123 cm. Its length is not stated but from the relative dimensions in their diagram it appears to have been of the order of 5 cm, giving a surface area of 0.019 cm.⁵

Thermionic emission from a fully thoriated wire at 1100°K is⁵ 2.51×10^{-6} amps per cm^2 corresponding to an emission of 4.77×10^{-8} amps from an area of 0.019 cm^2 . The Schottky effect at a field of 0.7×10^6 volts per cm would increase the thermionic emission to 1.35×10^{-6} amps; at this field Millikan and Eyring observed an increase in the emission of 0.02×10^{-6} amps. At a field of 1.0×10^6 volts/cm the thermionic emission would be 2.58×10^{-6} amps while the observed increase was 3.0×10^{-6} amps. The thermionic emissions have been computed for a fully thoriated surface, but taking into account the uncertainties in the measurements the observed increases appear to be of the order of magnitude of the possible thermionic currents, even if the surface were not completely thoriated. The experiments of Millikan and Lauritsen do not therefore establish the existence of a dependence of the autoelectronic emission on temperature.

THE RESULTS OF MILLIKAN AND LAURITSEN

Millikan and Lauritsen⁴ have recently published some new data in which proper allowance can be made for the thermionic emission taking into account the Schottky effect. Unfortunately the new data are limited to one graph in which only two points are relevant. Up to 800°K the current was constant at 4.6×10^{-8} amperes, at 1130°K (a temperature at which the thermionic current was negligible) the current was 5.6×10^{-8} amperes, at higher temperatures a thermionic current set in. These results therefore show a temperature variation which cannot be explained as due to a thermionic emission. Yet the position as left by the publication of Millikan and Lauritsen's paper is far from satisfactory, since it is impossible to have any confidence in a conclusion based on a few measurements of an effect in which it is extremely difficult to obtain reproducible results.

AUTHOR'S FIRST RESULTS

I first repeated Millikan and Lauritsen's experiment. A constant voltage was applied to a tube and the filament temperature was raised and lowered rapidly in fixed steps, the emission being noted at each step. The voltages used varied between 12,000 and 23,000 volts. A number of experimental runs were carried out. The results were quite inconclusive; two showed an increase in the autoemission at 1100°K of the order of magnitude observed by Millikan and Lauritsen, one showed a decrease in the emission, but the majority gave a series of widely scattered points through which it was impossible to draw any smooth curve; in general the spontaneous fluctuations in the emission were found to be of the order of magnitude of the increase observed by Millikan and Lauritsen. In plotting characteristics showing the variation of emission with field these fluctuations are far less disturbing because of the tremendous increase in the current produced by a comparatively small rise of field, but in an experiment such as this where the field is kept constant the spontaneous variations become relatively important. It was obvious that a new method of attack was required, and it was decided to obtain a continuous record of the galvanometer deflection.

RESULTS BY IMPROVED METHOD OF INVESTIGATION

The author observed that in some tubes the filament changed its shape considerably when heated and that such distortion was accentuated when a strong field was applied. The same difficulty has been noted by I. Langmuir and K. H. Kingdon⁶ in their work on contact potentials. The author therefore used tungsten wire of 0.02 mm diameter instead of the finest wire available. The filament of length was formed into a stable sharp angled loop inside a cylindrical anode closed at one end. The filament leads were encased in glass leaving only the filament exposed. The tubes were exhausted under the same conditions as a transmitting valve, the filament was outgassed and the anode was kept at bright red heat for twenty minutes before sealing off. After sealing off the filament was lit for some time with an applied anode voltage of 10,000 volts.

The galvanometer deflection was recorded photographically on a rotating drum which revolved once in about two minutes. A constant voltage from a valve rectifier set was applied to the experimental tube and the filament temperature was raised, for periods of about ten seconds, from room temperature to some other higher temperature which was fixed for each run. The periods when the filament was hot were recorded on the drum by the lighting of a small lamp which left a trace on the photographic paper. A calibration and zero line were also recorded. In all the curves the time axis increases from right to left.

Fig. 1. Galvanometer record. Applied potential 5,500 volts, filament heating current 0 and 0.235 amp.

Fig. 1 shows the record obtained when the voltage was too low to produce an autoemission. The small regular rises in the emission correspond to the periods when the filament temperature was raised to 0.235 amps [giving a temperature of 1600°K approximately]; 5500 volts were applied to the anode. It will be seen that at 5500 volts a measurable thermionic emission begins at a filament current of 0.235 amps.

Figs. 2, 3, 4, 5 show results obtained with an applied potential of 17,800 volts (corresponding to a field strength of 1.4×10^6 volts per cm). The first signs of any correlation between the emission and the periods of heating occur between a filament current of 0.220 and 0.230 amps. i. e. between 1550°K and 1600°K; it is in just this temperature range that a thermionic current is to be expected.

Figs. 6, 7, 8, 9, 10 show results obtained at an applied potential of 14,800 volts corresponding to a field of 1.2×10^6 volts per cm. Here again the first signs of any increase occur when the filament current is raised to 0.230 amps, corresponding to a filament temperature of 1590°K. Thus no measurable

⁶ I. Langmuir and K. H. Kingdon, *Phys. Rev.* 34, 129 (1929).

increase in the autoemission takes place up to about 1600°K at which temperature a thermionic emission sets in.

It seems probable that the electrons pulled out by strong fields must come in the main from energy levels lower down than those from which the ther-

mionic emission takes place, since within the limits of experimental error the autoemission is independent of temperature. Unfortunately Sommerfeld's theory can give no information on the temperature dependence, beyond showing that it must be small, since no exact measurement of the applied field is yet possible.

VARIABLE FLOW IN PIPES

BY H. BATEMAN

CALIFORNIA INSTITUTE OF TECHNOLOGY, PASADENA

(Received December 9, 1929)

ABSTRACT

The problem considered is that of finding a variable pressure gradient or forced motion of the pipe in a longitudinal direction which, at the time when it ceases to act, will have produced a prescribed distribution of velocity over the cross-section of the pipe. The subsequent changes in the distribution as the motion decays are also investigated and the cases examined point to the conclusion that an initial velocity profile with curvature of one sign will retain this property as it changes into the profiles for the different stages of the decaying motion.

INTRODUCTION

THE subject of variable flow in pipes is of much importance in engineering and has been studied experimentally in the case when the motion is turbulent. The problems which arise in connection with the metering of gases have been ably discussed by Hodgson,¹ Swift,² Judd and Pheley.³ Accelerated flow without pulsations has been studied by Gibson⁴ and Aisenstein⁵ who express the time necessary to reach a velocity v in the form

$$t = (K/2V) \log \frac{V+v}{V-v}$$

where V is the final velocity of steady flow under the force or pressure gradient which produces the constant acceleration and K is a coefficient which has one value for the Poiseuille régime and another value for the Venturi or turbulent régime, K depending in each case upon the value of the Reynolds number at time t .

We shall study here problems relating to flow in the Poiseuille régime when the acceleration is variable. For simplicity the compressibility of the fluid is neglected. This is undoubtedly a defect because in the particularly interesting case of rapid oscillations the motion will be complicated by the propagation of waves.

The propagation of waves in water has been much studied in connection with the phenomenon of water hammer in pipes and need not be discussed here. The propagation of air waves along a pipe, when viscosity is taken into consideration, has been studied theoretically by Stokes, Kirchhoff and Rayleigh.⁶

⁶ See Lamb's Hydrodynamics, pp. 612-617.

The recent experiments of Simmons and Johansen⁷ indicate, however, that there is need of further mathematical investigations. The author is considering the problem of pulsations when both viscosity and compressibility are taken into consideration but the work is not sufficiently advanced to warrant publication.

1. *Free decay, motion initially prescribed.* 'A long straight pipe of uniform cross-section has its ends attached by flexible connections to two reservoirs containing water, the pipe itself being supposed to be at any time completely filled with water.

The pipe is now moved in the direction of its length with a varying velocity $P(t)$. If u is the velocity of the water at the point (x, y, z) at time t the direction of motion being that of the axis of x , the equation of motion of the water relative to axes fixed relative to the reservoirs is

$$\rho \frac{\partial u}{\partial t} = \mu \left(\frac{\partial^2 u}{\partial y^2} + \frac{\partial^2 u}{\partial z^2} \right) - \frac{\partial p}{\partial x} + \rho X$$

where p is the pressure, ρ is the density of the water, μ its viscosity and X the external force per unit mass. If the water is treated as incompressible and the pipe as rigid, the equation of continuity

$$\frac{\partial \rho}{\partial t} + \frac{\partial}{\partial x} (\rho u) = 0$$

reduces to $\partial u / \partial x = 0$ and implies that $u = F(y, z, t)$. We shall assume moreover that ρ and μ are constants independent of position and of the time t .

If we write $u = U + P(t)$ where U is the velocity of the water relative to the pipe, the equation for U is

$$\rho \frac{\partial U}{\partial t} = \mu \left(\frac{\partial^2 U}{\partial y^2} + \frac{\partial^2 U}{\partial z^2} \right) - \frac{\partial p}{\partial x} - \rho \frac{dP}{dt} + \rho X$$

and so the motion relative to the pipe is the same as if the pipe were at rest and the fluid acted upon by an additional body force $-P'(t)$ per unit mass or an equivalent pressure gradient $\rho(P't)$. When p and X are zero the free motion in an oscillating pipe is relatively the same as the forced motion in a stationary pipe when the external force or pressure gradient fluctuates in the prescribed manner.

The transfer of motion from an oscillating plane to an adjoining liquid has been studied by Stokes,⁸ Rayleigh⁹ and other writers. Stokes showed that when the frequency of oscillation is high the motion in the fluid rapidly diminishes in intensity as the distance from the plane increases. This indicates that if fluid bounded by parallel plane walls is set in motion by a rapidly fluctuating pressure gradient which oscillates about a zero value, the

distribution of velocity over the cross-section will be approximately uniform except in the immediate neighbourhood of the walls, where rapid variations are to be expected. This result has been extended by S. F. Grace¹⁰ to the case of flow in a pipe of circular section. For a pipe of radius 1 cm there is approximate uniformity in the distribution of velocity over a large part of the cross-section if the period of oscillation is less than six seconds. The velocity moreover, lags 90° in phase behind the force producing the motion.

The existence of a phase lag indicates that the water may still be moving when the driving force has ceased to act. If, then, we go back to the case of the moving pipe we can say that the water may still be moving when the pipe is brought to rest. The velocity distribution at this time ($t=0$, say) may, indeed, be prescribed more or less arbitrarily so long as the velocity at the boundary is zero. Some interesting questions now arise with regard to the manner in which the velocity profile changes as the motion dies down.

Suppose, for instance, that the velocity profile has initially curvature of only one sign so that, when the velocity at each point of the cross-section is represented by an ordinate MQ , the locus of Q is everywhere concave to the plane of the section. It is interesting to inquire whether at some later time t the velocity profile can be partly convex to the plane of the section. This question is an interesting one because in his studies of the stability of an inviscid incompressible fluid in rectilinear motion between parallel planes Lord Rayleigh¹¹ found that a steady motion, without changes in the sign of the curvature of the velocity profile, was stable for small oscillations but that a profile with changes in the sign of the curvature might be unstable.

The question has been studied for the case of flow between parallel planes $z = \pm a$, the free motion being represented by

$$u = c_1 e^{-s} \cos \theta + c_3 e^{-9s} \cos 3\theta + c_5 e^{-25s} \cos 5\theta + \dots$$

where $s = \nu \pi^2 t / 4a^2$ and $\theta = \pi z / 2a$. The expansion was limited to the first three terms and the coefficients c_1, c_3, c_5 were chosen so that the coefficients of z^2 and z^4 in the Taylor series for u were initially zero. This gives an initial distribution of velocity with curvature of one sign and a nearly constant value for a large part of the cross-section. The numerical work gave no indication of a change in sign of the curvature at any point of the profile as it changed with the time. The profile, in fact, gradually approached the shape of the cosine curve $u = k \cos \theta$ which differs only slightly in shape from the parabola characteristic of steady motion.

The question was also examined by assuming that at time $t=0$

$$d^2u/dz^2 = -\cos \theta [(\alpha \cos^2 \theta + \beta)^2 + \gamma^2]$$

where α, β and γ are constants. Again there was no indication that at a later time t it would be legitimate to write

$$d^2u/dz^2 = -\sigma \cos \theta [\cos^2 \theta - \cos^2 \theta_1][\cos^2 \theta - \cos^2 \theta_2]$$

where θ_1 and θ_2 are real angles.

In the work of Grace the oscillations were undamped. To discuss a type of variable motion which ceases at time $t=0$ we first consider the case in which

$$\begin{aligned} P(t) &= (-\nu t)^{-1/2} \exp(m^2/4\nu t) & t < 0, \\ P(t) &= 0 & t > 0, \end{aligned}$$

where $\nu = \mu/\rho$ is the kinematic viscosity. Since $\partial u/\partial t = \nu \partial^2 u/\partial z^2$ and

$$P(t) = K \int_0^\infty e^{\xi^2 \nu t} \cos(m\xi) d\xi, \quad t < 0,$$

where $K = 2/\sqrt{\pi}$, an appropriate solution is

$$u = K \int_0^\infty e^{\xi^2 \nu t} \cos(m\xi) \cosh(z\xi) \operatorname{sech}(a\xi) d\xi \quad t < 0.$$

As $t \rightarrow 0$, $u \rightarrow u_0$, where

$$\begin{aligned} u_0 &= K \int_0^\infty \cos(m\xi) \cosh(z\xi) \operatorname{sech}(a\xi) d\xi \\ &= \frac{(2K/a) \cosh(m\pi/2a) \cos(z\pi/2a)}{\cosh(m\pi/a) + \cos(z\pi/a)}. \end{aligned}$$

When $\sinh^2(m\pi/2a) = \frac{1}{2} u_0$ is approximately constant over a considerable part of the cross-section. If, however, we take $\pi^2 m^2/4a^2 = 1/32$, we have the result that u_0 is approximately proportional to

$$\frac{65 \cos \theta}{4 + 128 \cos^2 \theta}.$$

When $z=0$ this fraction is equal to $65/132$ and when $z=2a/3$ the fraction is equal to $65/72$. It should be noticed that the maximum value of $P(t)$ occurs when $2\nu t = -m^2$, the maximum value being $(m^2 e/2)^{-1/2}$. Hence a small value of m corresponds to a large maximum velocity of the walls.

The present result confirms our statement that the fluid may still be moving when the pipe has ceased to move.

To discuss the decay of the motion when $t > 0$ we expand u_0 in the form

$$u_0 = H \sum_{s=0}^{\infty} (-)^s e^{-mS} \cos(zS)$$

where $S = \pi(2s+1)/2a$ and $H = 4\sqrt{\pi}/a$. The velocity at time t is then

$$u = H \sum_{s=0}^{\infty} (-)^s e^{-mS - \nu S^2 t} \cos(zS).$$

Since u satisfies the equation $\partial u / \partial t = \nu \partial^2 u / \partial z^2$ the velocity $u^{(n)}$ corresponding to a function

$$P^{(n)}(t) = \frac{\partial^n}{\partial t^n} P(t)$$

$$u^{(n)} = \nu^n \frac{\partial^{2n} u}{\partial z^{2n}}$$

is

$$= K \nu^n \int_0^\infty e^{\xi^2 \nu t \xi^{2n}} \cos(m\xi) \cosh(z\xi) \operatorname{sech}(a\xi) d\xi \quad (t < 0)$$

$$= H \nu^n \sum_{s=0}^\infty (-)^s + n S^{2n} e^{-mS - \nu S^2 t} \cos(zS) \quad (t > 0).$$

An initial distribution of velocity

$$\bar{u}_0 = H \sum_{s=0}^\infty (-)^s \phi(-\nu S^2) e^{-mS} \cos(zS)$$

will, with a suitable form of the function ϕ , be produced by a velocity of the walls varying up to time 0 according to the law

$$\bar{P}(t) = \phi\left(\frac{\partial}{\partial t}\right) P(t).$$

2. *Forced motion.* We next consider the equation

$$\rho \frac{\partial u}{\partial t} = \mu \frac{\partial^2 u}{\partial z^2} - \frac{\partial p}{\partial x}, \quad (\mu = \rho \nu)$$

for the rectilinear flow of an incompressible viscous fluid of constant density ρ when the pressure gradient $\partial p / \partial x$ varies with the time. For convenience we write

$$-\frac{\partial p}{\partial x} = \left(\frac{2\mu}{\pi}\right) \int_0^\infty e^{-\nu m^2 t} \cos ma \cdot dm \int_0^\infty \cos mv \phi(v) dv$$

where $\phi(v)$ is an even function for which Fourier's integral formula may be used with confidence. The corresponding expression for u is then

$$u = (2/\pi) \int_0^\infty e^{-\nu m^2 t} (\cos mz - \cos ma) (dm/m^2) \int_0^\infty \cos mv \phi(v) dv.$$

It should be noticed that at time $t=0$ we have

$$-\frac{\partial p_0}{\partial x} = \mu \phi(a)$$

$$u_0 = \int_z^a ds \int_0^s \phi(v) dv.$$

If, on the other hand we write $f(m)$ instead of $\int_0^\infty \cos mv \phi(v) dv$ and take $f(m)=1$ we have

$$-\frac{\partial p}{\partial x} = \mu(\pi \nu t)^{-1/2} e^{-a^2/4\nu t}, \quad \text{and}$$

$$u = (\pi \nu t)^{-1/2} [F(a, t) - F(z, t)], \quad \text{where}$$

$$F(z, t) = \int_0^z (z-s) e^{-(s^2/4\nu t)} ds.$$

A short table of values of $F(z, t)/2\nu t$ is given below. For convenience n has been written for $z/2(\nu t)^{1/2}$ and values of e^{-n^2} are also included. The fifth figure in the decimal may be slightly incorrect.

For the case in which $a=2$ the distribution of velocity has been calculated at times t for which $2(\nu t)^{1/2}$ has the values 1, 2, 4, respectively and compared with the parabolic distribution for steady flow. In each case the velocity is compared with the axial value c . The third time is beyond that at which the pressure gradient is a maximum. It will be noticed that while the pressure gradient is increasing the distribution of velocity differs only slightly from the distribution for steady flow. When t is large we have $F(z, t) = z^2/2 - z^4/48\nu t$, approximately, and so in the final stages of the motion the distribution of velocity again differs only slightly from the parabolic distribution.

TABLE II
 z/a

$2(\nu t)^{1/2}$	0	0.2	0.4	0.6	0.8	1	
1	1	0.9384	0.7724	0.5393	0.2751	0	u/c
2	1	0.9307	0.8191	0.6054	0.3273	0	u/c
4	1	0.9584	0.7512	0.6307	0.3508	0	u/c
Parabola	1	0.96	0.79	0.64	0.36	0	u/c

3. The analysis for rectilinear flow in a tube of circular section is very similar to that for flow between two parallel walls. The equation of motion is now

$$\rho \frac{\partial u}{\partial t} = \mu \left(\frac{\partial^2 u}{\partial r^2} + \frac{1}{r} \frac{\partial u}{\partial r} \right) - \frac{\partial p}{\partial x},$$

where r is the distance of a point from the axis of the tube. We shall commence with a study of forced motion.

If

$$-\frac{\partial p}{\partial x} = \mu \int_0^\infty e^{-\nu m^2 t} J_0(ma) m dm \int_0^\infty J_0(mv) \psi(v) v dv$$

where $\psi(v)$ is a function for which the inversion formula of Hankel may be used with confidence, the corresponding expression for u is

$$u = \int_0^\infty e^{-\nu m^2 t} [J_0(mr) - J_0(ma)] (dm/m) \int_0^\infty J_0(mv) \psi(v) v dv$$

and at time $t=0$ we have

$$\begin{aligned} -\frac{\partial p}{\partial x} &= \mu \psi(a) \\ u_0 &= \int_r^a (ds/s) \int_0^s v \psi(v) dv. \end{aligned}$$

Another particular case of interest is that in which

$$\begin{aligned} -\partial p / \partial x &= (\mu / 2\nu t) \exp [-a^2 / 4\nu t] = \mu \int_0^\infty e^{-\nu m^2 t} J_0(ma) m dm \\ u &= \int_t^\infty (d\tau / 2\tau) [\exp (-r^2 / 4\nu t) - \exp (-a^2 / 4\nu t)]. \end{aligned}$$

Next, taking the case of free motion, let us suppose that the velocity of the pipe at time t is given by the function $P(t)$, where

$$\begin{aligned} P(t) &= (-1/2\nu t) \exp (g^2/4\nu t) & t < 0 \\ P(t) &= 0 & t > 0 \end{aligned}$$

Since

$$P(t) = \int_0^\infty e^{\nu m^2 t} J_0(mg) m dm \quad t < 0$$

an appropriate solution is

$$u = \int_0^\infty e^{\nu m^2 t} J_0(mg) m dm [I_0(mr) / I_0(ma)], \quad t < 0$$

with the usual notation for the Bessel function with imaginary argument.

As $t \rightarrow 0$, $u \rightarrow u_0$, where

$$u_0 = \int_0^\infty J_0(mg) m dm [I_0(mr) / I_0(ma)]$$

IONIC MOBILITIES IN Cl_2 AND IN Cl_2 -AIR MIXTURES

BY LEONARD B. LOEB

UNIVERSITY OF CALIFORNIA, BERKELEY

(Received December 9, 1929)

ABSTRACT

Work of early investigators and of Herbert Mayer indicates that the presence of traces of Cl_2 reduces the mobility of the negative ion below that of the positive ion, a fact which appeared inconsistent with a theory of Condon and the writer. No investigations of mobilities of both ions in pure Cl_2 have been reported. The possibility that the discrepancy between theory and observation in Mayer's results was caused by HCl in the Cl_2 made a more careful investigation imperative. Cl_2 carefully prepared and free from both HCl and H_2O was used. It was found that the values of the mobilities in pure Cl_2 on the new absolute standard for positive and negative ions was 0.654 and 0.510 cm/sec per volt/cm respectively. A study of mixtures of dry air and Cl_2 showed that traces of Cl_2 less than 0.1 percent reduce the negative mobility below that of the positive ion. The positive mobilities were little affected by the presence of Cl_2 so that while positive ions obey Blanc's law in Cl_2 -air mixtures the negative ion shows a marked clustering effect. No disturbances due to dipole moments were observed for positive ions in Cl_2 as is to be expected.

INTRODUCTION

IN ATTEMPTING to determine something of the nature of the gaseous ions a study of mobilities of ions in gaseous mixtures has shown itself to be of value.¹ Later investigations have shown that beyond the more important conclusions already drawn from this study, further investigations will add but little of importance, until a much greater control of minute traces of impurity can be had.^{1,2} This appears to be the more so in view of the recent researches of Erikson.³ Before concluding the work on mixtures and turning to a new method of attack on the ion problem it was felt essential to study one more gas, to wit: chlorine, in view of certain apparent discrepancies in data and theory. So far ionic mobilities in pure chlorine have been studied by only one observer, Wahlin,⁴ and that for the *negative ion* only. His value for the negative ion mobility constant was 0.73 cm/sec per volt/cm. The interest in Cl_2 lies in the fact that all observers have reported⁵ that the *negative* mobility in Cl_2 appeared to be *less than* the *positive* mobility while according to Condon

¹ L. B. Loeb, Phys. Rev. **32**, 81 (1928).

² DuSault and Loeb, Proc. Nat. Acad. Sci. **14**, 384 (1928).

³ H. A. Erikson, Phys. Rev. **34**, 635 (1929).

⁴ H. B. Wahlin, Phys. Rev. **19**, 173 (1922).

⁵ To date no accurate observations on *both* ions in Cl_2 have been made. The effect of Cl_2 in mixtures of low percentage Cl_2 with other gases inferred by early observers and one very uncertain result of Mayer's at 8 cm pressure were the only data on which such assertions could be founded.

and the writer⁶ this should not occur for gases having a low dipole moment fairly symmetrically placed inside of the molecule, as in Cl_2 .

EARLY ATTEMPTS OF THE WRITER

In closing the work on the mobilities in mixtures for the spring of 1928 Miss L. DuSault and the writer therefore made a study of Cl_2 . In this case ordinary *grease lubricated stopcocks* were employed, and the Cl_2 was fractionated from a large tank loaned by the Chemistry department, liquid air being used, together with cooling traps to remove moisture. Two interesting facts were found in this work which was carried on with Cl_2 and occasionally Cl_2 mixed with H_2 , using pure H_2 as a control gas for calibrating the apparatus. The one fact was that Cl_2 yielded a positive mobility constant of 0.617 cm/sec per volt/cm and a negative mobility constant of 0.466 cm/sec per volt/cm under the conditions used. This is one of the cases where the negative mobility relative to the positive mobility is as low as it has ever been observed and appeared contrary to the theory of Condon and Loeb. Further certain uncontrollable irregularities were observed in some of these cases in which the presence of traces of Cl_2 in pure H_2 caused phenomenally high values of the positive ion mobilities. An analogous result had been observed to a smaller extent in the SO_2 - H_2 ² mixtures, but in the case of Cl_2 the values of the positive mobility were so high, (i.e. in one or two cases three times the normal mobility in H_2) that a further study seemed suitable.

In all these studies it was observed that when the ionization chamber was opened for cleaning to remove the last traces of Cl_2 a strong odor of HCl was present, even after prolonged pumping. This was found to be due to the extensive reaction of Cl_2 with the organic stopcock grease which emitted HCl for hours after exposure to Cl_2 .

On resuming work in the fall of 1928, the abnormally high positive mobilities persisted in an unpredictable fashion, even after all the apparatus up to the mercury vapor pump had been carefully cleaned. At this stage of the work it had never been found essential to place a liquid air trap between the pump and the chamber as Hg vapor has no material effect on the ions. It then was suspected that the Cl_2 acting on the Hg had produced HgCl_2 which on heating in the pump gave off Cl_2 and so produced the spurious high values mentioned. On cleaning the pump and using fresh Hg no more values of this sort were observed. The facts which seemed apparent as far as the high values of positive mobilities were concerned could be summed up as follows. The presence of either traces of SO_2 or more especially Cl_2 from the mercury vapor pump in traces sometimes seemed to cause this effect which could never be controlled. It became an urgent problem to attempt to discover the cause of this effect if possible.

The low values of the negative mobilities in Cl_2 relative to the positive values, and the practically non-polar nature of Cl_2 , led the writer to look for this lowering in the presence of HCl due to stopcock greases and due to HCl in the Cl_2 from the tank which could not be removed by fractionation.

⁶ L. B. Loeb, Phys. Rev. 32, 95 (1928). Also Kinetic Theory of Gases, p. 478.

THE PREPARATION OF PURE Cl_2

Beginning in the spring of 1929 and extending well into the autumn attempts were made to develop a system for generating Cl_2 free from H_2O and HCl , and devise greaseless stopcocks. The trouble with the use of mercury seal stopcocks lay in the large number of cocks required, the dangerous nature of large quantities of Cl_2 gas in case of failure of the mercury seal stopcocks and the constant "freezing" of such stopcocks with large pressure differences and constant use. The problem was finally solved as follows.

For the apparatus a large number of mercury seal type of stopcocks of a high quality were made for this work by Mr. L. B. Clark, then departmental glass blower. The design of these is shown in Figure 1. In place of ordinary

Fig. 1. Design of mercury-seal stopcocks.

lubricants a paste of P_2O_5 and water was made by dissolving as much P_2O_5 in a small amount of water as possible. This was achieved by heating to 250 or 300°C in a porcelain dish. The paste on cooling was like a very thick syrup in consistency. Trouble was experienced at first in that the P_2O_5 of *best quality* for drying tubes furnished by standard chemical concerns *contained marked amounts of P_2O_3* . On mixing with water local heating and steam production resulted in the reduction of P_2O_3 to P, which on heating or otherwise changed to the red form. The presence of this substance was confirmed by the dull red color, the odor and the flashes of flame at the surface of the paste as the temperature rose above 250°C. It might be noted that the pink color taken on by P_2O_5 in drying trains as it hydrates where organic matter is avoided is due to

the formation of this substance. By either getting a good grade of P_2O_5 , which rarely happens, or by subliming the P_2O_5 for long hours at a reasonably low temperature, (below the melting point so as not to attack the glass) in a stream of O_2 the pentoxide may be prepared free from such substances. In the results to be given earlier measurement were made with P_2O_5 lubricant containing red phosphorus. The fear that Cl_2 might react in traces with P led to the use of later lubricants treated as above and free from this source of trouble. As it turned out the results were apparently not influenced by this impurity.

In using P_2O_5 paste as a lubricant care must be taken to have the moisture of the air kept from the paste on the stopcocks. Accordingly the surface of the P_2O_5 was covered with a pure mineral oil in the cup part C of the stopcocks. The system was always first dried out carefully before lubricating and replacing the stopcocks. As long as the gases inside were dry the lubricant on the beautifully ground stopcocks made for us behaved very well even under pressure differences of 1 atmosphere and with frequent turning. Gradually however the lubricant "worked" out of the cocks on constant use, (25 to 50 turnings over a period of a week) and had to be renewed.

The Cl_2 was generated by a method previously used by Professor Rollefson of the Chemistry department. $CuCl_2$ deprived of most of its water by heating and stirring under a hood was placed in heavy Pyrex glass bulbs surrounded by heating coils. These were heated in vacuo gradually beginning at $200^\circ C$ for some 10 to 20 hours increasing the temperature step by step to 250° in 3 hours, to 300° in 3 more hours, to 350° in 4 hours and held at close to 400° for some 4 hours. Under these conditions no more water or HCl was observed to come off and Cl_2 began to appear. The temperature was then raised rapidly to from 450° 500° and the first fraction of Cl_2 was run down the drain by using a Nelson oil pump which permits the exhaust being run into a drainpipe of the sink directly. The pump with liquid air trap protecting it was then cut off and the Cl_2 generated into a trap cooled with liquid air. After enough had distilled over, the heat was reduced and the first fraction of the Cl_2 run into the trap protecting the pump by opening the proper stopcock. The central fraction was then distilled into a storage trap adjoining the mobility apparatus and kept frozen with liquid air until needed. The last fraction and the material in the protecting trap to the pump were then rapidly exhausted through the pump to the drain by warming the traps with the hand. The oil in pumps used this way needs frequent changing to prevent rusting of the pump due to the HCl from the reaction of the oil with Cl_2 . In this way the experiments were carried on with no exposure to Cl_2 on the part of the workers although dangerously large quantities of liquid Cl_2 were used. When in removing the last parts of Cl_2 -air mixtures by the Cenco and diffusion pumps from the ionization chamber into the air of the room the noxious effects of the Cl_2 in the room were considerably ameliorated by the free use of NH_4OH about the escape vents. The NH_3 gas by protecting mucous membranes from the action of HCl saved all the Cl_2 workers from bad chlorine colds.

THE MEASUREMENTS

In other respects the measurements were carried out by the standard methods employed by the writer^{1, 2, 7} in other mixtures, except for the use of a liquid air trap between the mercury vapor pump and ionization chamber. A brand new freshly gold plated chamber was used for this work with a spring contact device to insure good metallic contact between the upper plate and the outside. In the previous designs the contact had been made by the pressure of the threads in the tube supporting the upper plate against the threads of the supporting rod. The chamber was made gas tight as before by a pressure joint on a lead gasket. To prevent slow leaks the *outside* of the lead joint at the gasket was covered with an oily heavily chlorinated hydrocarbon called commercially chloracosan, which does not react with Cl_2 and is employed medicinally for use in chlorine applications, as it does not react to form HCl . This was kindly suggested to the writer by Dr. Felix Lengfeld, formerly of the University of California.

The measurements were nearly all made using an auxiliary field with 12 volts between gauze and lower plate over 1.2 cm. The plate distance used was about 1.0 cm, and in most cases the alternating potential at which the ions crossed was fixed so as to be 30-40 volts. Where the ions crossed at lower or higher alternating potentials correction was made for the interpenetration of

THE MOBILITIES OF IONS IN Cl_2 .

It is seen from Tables I and II that the values of the mobilities were closely the same in the early measurements and in those with purer Cl_2 . It is also seen that the presence of red P in the lubricant did not change the values within the limits of error. The values were all averaged together, the newer values being weighted twice the old ones. This gives the final values as 0.604 cm/sec per volt/cm for positive ions and 0.471 cm/sec per volt/cm for negative ions under the experimental conditions mentioned above. Corrected for the effects of the interpenetrating fields^{2, 8} the mobilities in terms of the old accepted air standard of 1.4 and 1.8 cm/sec per volt/cm, and on the new absolute scale come out in cm/sec per volt/cm as

+ ions	- ions	
0.544	0.424	old scale
0.654	0.510	new absolute scale

The negative value obtained is lower than that of Wahlin⁴ obtained at lower pressures with undefined conditions of auxiliary field strength, and about of the order observed by Mayer's confessedly uncertain values at 8 cm pressure.⁹

THE WORK IN MIXTURES OF Cl_2 AND AIR

In spite of Mayer's work on the air mixtures from 1 to 4.5 percent Cl_2 , it was considered worthwhile to extend measurements in the mixture to higher concentrations using the pure Cl_2 . To study the effects of mixtures of dry air and Cl_2 the following set of values were observed for a field strength from 30-40 volts for bringing ions across, and an auxiliary field of 10 volts/cm. The uncorrected values were used to give the comparison of the mobilities with those computed from the law of mixtures of Blanc,¹⁰ using the reciprocals of the mobilities instead of the mobilities as is the custom in the more recent work.¹

TABLE III. Mobilities in mixtures of Cl_2 and air.

Mol fraction <i>f</i> of Cl_2	Mobility constants		Mol fraction <i>f</i> of Cl_2	Mobility constants

If the reciprocal of the mobility be written $R_f = 1/K_f$ (virtually the resistance to motion of the ion), then in a mixture containing a mol fraction *f* of Cl_2 , the reciprocal of the mobility according to Blanc's¹⁰ law should be given by

$$R_f = fR_{\text{Cl}_2} + (1-f)R_{\text{air}},$$

⁹ Herbert Mayer, Phys. Zeits. 27, 513 (1926) and 28, 637 (1926).

¹⁰ A. Blanc, Jour. Physique 7, 825 (1908).

where R_{Cl_2} and R_{air} , are computed from the observations above, using the data actually observed for an auxiliary field of 10 volts/cm and an alternating field of 30-40 volts. The results are thus merely relative and not absolute, but could be reduced to absolute values by using the appropriate factors given in the reduction of the observed mobility in Cl_2 to the absolute scale.

The results observed are shown by the experimental points as crosses for positive ions and circled points for negative ions joined by the dashed lines in Figure 2. The full straight lines are computed from the Blanc's law above for this mixture and appropriately labelled as to sign.

Fig. 2. Reciprocal of mobility as function of concentration of Cl_2 in a Cl_2 -air mixture.

The early measurements of Mayer⁹ from 1 to 4.5 percent Cl_2 are indicated by the triangles for negative ions and squares for positive ions. The positive observations of Mayer were multiplied by a factor to make Mayer's low positive values in air and air- Cl_2 mixtures coincide with the writers' for pure air. The reason for Mayer's low positive values in air lies in the fact that Mayer's apparatus due to lack of experimental facilities contained impurities which gave him a low positive mobility in air compared to negative values, (i.e. some organic vapors from his ebonite insulators). It is seen that Mayer's points for the negative ions agree remarkably well with the writers, considering the differences in technique used, and that on reduction to the same scale Mayer's positive ions show the same relative change in mobility as the writer's within experimental uncertainty.

DISCUSSION

It is seen at once that the positive mobilities lie along the Blanc's law curve within the limits of experimental accuracy. This indicates that the *positive ions do not react specifically with Cl_2 molecules to form clusters*. As the dielectric constant of Cl_2 is low the effect of dielectric attractions observed in gases like HCl , SO_2 and NH_3 ^{1,7} are absent as shown by agreement with

Blanc's law. It is further seen that the *negative ions have mobilities which drop from values of 2.00 to about 1.4 cm/sec for concentrations less than 1/2 of one percent*. The negative ions suffer therefore a very large, (perhaps the largest), decrease of mobility observed for additions of traces of any active gases to gases like air. This means not only a *specific cluster formation of Cl₂ about the negative ions but also a large cluster and a stable one*. It is also clear that this is due to some electrochemical affinity which is not caused by a high dielectric constant, for that of Cl₂ is low.

According to Blanc's law for Cl₂ the positive and negative ions should have equal mobilities at about 20 percent. This is also the value at which the positive and negative mobilities were *observed* to be equal for HCl. In these experiments traces of Cl₂ too small to measure made the mobilities of positive and negative ions equal. In Mayer's results as observed, due to an abnormal lowering of Mayer's positive mobilities by other impurities, the two mobilities were found equal at about 1 percent. This result as Mayer⁹ has already pointed out indicates that the lowering of the negative mobility in his experiments was not due to HCl. The writer's work confirms this conclusion further by the use of Cl₂ free from HCl.

No trace of the capricious high positive mobilities with traces of Cl₂ were observed in the later experiments of the writer, even with the absence of the liquid air trap near the diffusion pump, and with the use of hydrogen as in earlier work. This may indicate that such results as mentioned earlier in this paper for Cl₂ and possibly also for SO₂² were due to imperfect electrical contacts in these reactive gases. In any case they were not reproduced in the present work and their uncontrollable appearance must be taken as an indication that they are spurious, and to be regarded with caution.

CONCLUSIONS

The conclusions to be drawn from these results are as follows: (1) The high irregular positive mobilities mentioned elsewhere in SO₂² and found in preliminary work in Cl₂ appear to be of a spurious origin, and must not be regarded seriously. (2) Cl₂ has no effect on the positive ion other than that predicted by Blanc's law and the mobility of this ion varies in Cl₂-air mixtures in much the same fashion as in H₂²-air or CO₂-air mixtures. There is no indication of a stable large cluster formation about the positive ion in Cl₂ and no indication of the effect of a high dielectric constant, as is to be expected as Cl₂ is said to be non-polar. (3) The negative ion shows a marked affinity for Cl₂ molecules. Cl₂ obviously forms a large and stable cluster about the negative ion even when present in minute traces. (4) The lowering of the mobility of the negative ion below that of the positive ion for traces of Cl₂ *must be ascribed to this cluster formation, due to a totally unexplained electro-chemical mechanism. It cannot be accounted for by the existence of an unsymmetrical dipole of large moment in the Cl₂ molecule*, which is a viewpoint put forward by Condon and Loeb⁶ to explain the decrease of the negative mobility below the positive mobility in the cases of HCl, SO₂, H₂O, H₂S and other substances. It is surprising that this type of action should occur with the *Cl₂ molecule* since this *molecule* appears to have satisfied the strongly electronegative tendency of the

Cl_2 atoms relative to its other physical reactions in its formation. The chemical reactivity of Cl_2 on the other hand is due to a low heat of dissociation, and supposedly not to other properties of the Cl_2 molecule. The action on the negative ion is presumably analogous to the action of ethyl ether or NH_3 on the positive ions, yet how and why it takes place is in no sense clear.

With this work the writer is closing his investigation of mobilities in mixtures using the methods in which the mobilities of *unknown carriers are determined in gases where the carriers make 10^7 or more impacts with neutral gas molecules in the time of measurement.* In such cases purities of substances are required that are beyond chemical control. It is hoped that a new method which is being developed will enable the mobilities of ions of a known nature to be studied under conditions where impurities do not play the important role which they play in the usual measurements.

In concluding the writer desires to express his sincere thanks to his colleague Professor J. H. Hildebrand for his valuable advice in solving some of the many chemical difficulties encountered, to Miss L. DuSault who cooperated in the earlier measurements, and finally to his friend and research assistant Commander T. Lucci, late of the Italian Navy for his untiring assistance in the tedious work of preparation of and measurements in pure Cl_2 .

ON MECHANICAL AND MAGNETIC FACTORS INFLUENCING THE ORIENTATION AND PERFECTION OF BISMUTH SINGLE-CRYSTALS

BY ALEXANDER GOETZ
CALIFORNIA INSTITUTE, PASADENA

(Received December 12, 1929)

ABSTRACT

Method of producing crystals of bismuth.—A method is described which permits the production of single crystals of metals, with practically no limit to size or to desired orientation, thus indicating that all external mechanical influences are avoided. Furthermore, the method permits the zone of formation in a growing crystal to be subjected to a strong magnetic field.

Mechanical factors influencing the orientation and perfection of crystals.—A systematic study of the conditions in which the seed-crystal transfers its orientation to the rod is made. Experiments with artificially distorted seeds, etc., show that crystalline units must already exist in the liquid state. It is shown that this "liquid crystal" is destroyed at about 10° above the melting point. It is suggested that these units are identical with elementary units of a crystal as treated theoretically by Zwicky and observed by the author.

The influence of a magnetic field on a forming crystal.—Crystals in the three main orientations to the directions of the field lines (20,000 Gauss) were grown, one-half with, the other half without field. No change in the orientation between both halves could be observed as long as no secondary influence was present. However, crystals grown without a predetermined orientation indicated a preference for an orientation in which the direction of the smallest diamagnetic susceptibility (along the trigonal axis) was parallel to the lines of force. The fact that this influence, though much smaller than the orienting forces of a seed, exists, supports the assumption of "block-phase" slightly above the melting point.

INTRODUCTION

THERE are several reasons why a systematic investigation of the factors influencing the orientation and perfection of a metal crystal seems to be important. One of these reasons is the fact that certain methods of growing crystals succeed only for certain orientations, though the orientation is forced on the growing crystal by inoculation with a seed-crystal. Then it can happen that the desired orientation is only maintained over a short region or does not even start. In a previous paper,¹ Goetz and Hasler came to the same conclusion as Kapitza:² namely, that a growing crystal is very sensitive to any mechanical stress. Such stresses exist in almost every known method of crystal production. This necessitates the development of a new method which allows also the decision to be made as to whether this extremely sensitive region is in the solid part of the growing crystal or in the still liquid state.

¹A. Goetz and Maurice F. Hasler, Proc. Nat. Acad. 15, 646 (1929).

²P. Kapitza, Proc. Royal Soc. A119, 358 (1928).

Furthermore, it seemed to be interesting to see if directional forces of other than mechanical or thermal, especially magnetic, nature would show any influence when applied to the zone of formation. In spite of several papers written on this subject, no investigations excluding secondary effects have been systematically made. The results correlated from these papers contradict each other to some extent also.

THE METHOD OF PRODUCING CRYSTALS

After investigating the conditions for an unrestricted growth of Bi crystals by means of all known methods, it was found that these conditions can be summarized as follows:

(1) No strain of any kind should be applied to the zone of formation of the growing crystal.

(2) The crystal should not have any oxide-coat which can be the cause of stress.

(3) The speed of growth should be uniform.

(4) The heat gradient over the crystal should be uniform and its position within the crystal constant over the whole length.

(5) If the orientation of the crystal is to be predetermined by inoculation, it is necessary to obtain thermal equilibrium at the transition between seed-crystal and inoculated metal.

There is no method known which fulfills all these conditions equally well. However Kapitza's method, with which he produced the crystals finally used for his measurements, comes nearest, but it cannot be used for long crystals and does not satisfy condition (2).

Condition (1) seemed to me the most important one, and a large number of experiments were performed to fulfill it satisfactorily. One of the main troubles was that the molten metal (as soon as it was free from oxide) stuck to the walls of the container, thus interfering with the change of volume at crystallization. Many different arrangements were tried. For instance, a trough of thin paper was made in which the molten Bi was poured. When heated the paper carbonized, yet kept its shape sufficiently until the metal crystallized. The strength of these troughs was so small that the crystallizing metal could break them easily. Very uniform crystals were obtained by this method but the external shape was quite irregular. Finally, it was found that smooth troughs of Acheson graphite worked as well as the troughs of carbonized paper without having the disadvantage of losing their shape after the crystallization of the metal.

The final arrangement based on the previous experiences was the following: The troughs were shaped out of large blocks of Acheson graphite from a region free from fissures. The troughs had a length of 30 cm, were 0.4 cm wide and shaped rectangularly. Special precautions had to be observed in shaping to avoid deformations caused by the flexibility of the material. To fulfill condition (2) it was necessary to place the trough *G* in a glass or quartz tube *C* (in Fig. 1) which had at one end a ground-glass cone in which a little glass dome with a capillary was fitted. The cross-section of *C* was circular

over the whole length to within 3 cm of the cone, where it was as shown in the cross section (Fig. 1) elliptical to give more space above the trough. *F* was an electric furnace (chromel wire coiled around a quartz-tube) with two end plates, through the holes of which went the tube *C*, in such a manner that it did not touch the walls. The tube was supported at one end by means of the V-shaped adjustable holder *A* in which the tube glided over graphite wedges. The other end of the tube was supported at the clamp *O* which was a part of the driving arrangement fulfilling condition (3) (not shown in Fig. 1, because its design has already been published¹.) The connection between *O* and *C* was made with a rubber-tube *N* which absorbed to some extent the vibrations of the motor.

Fig. 1. Diagram of essential features of the apparatus.

The method of producing crystals was as follows: Round metal rods of 2–3 mm diameter were first made in glass tubes as described in another paper.¹ After the glass was taken off, the rods were cut down to a standard length of 120 mm (first generation).

The clamp *O* was then disengaged from the driving mechanism and moved towards the right so that the tube *C*, and with it the trough *G*, came out of the furnace *F* as far as possible. The glass dome was then removed and the rod placed in the trough. Then the tube was closed and the clamp *O* was put back into such a position that the end of the rod came out of the furnace *F* for a short distance. The furnace was restrictively heated so as not to melt the end of the rod. After the tube had come to thermal equilibrium with the furnace, the clamp *O* was engaged with the driving apparatus which moved

it in the direction of the arrow at a rate of 5 mm/min. To reduce the oxide at the surface of the rod a constant flow of hydrogen was sent through the tube. It soon became apparent that the purity of the hydrogen and the constancy of the flow were of great importance for the uniformity of the crystals, which made a rather elaborate arrangement necessary. The hydrogen was first taken from a tank with a reduction valve. To separate dust from the gas, it was then sent through a gas filter *B* and then through a heated tube with palladiumized asbestos to oxidize the impurities; thereafter through the trap *H*, cooled by liquid air, and then through the valve *D*. From here it went into the tube, over the metal and escaped through the capillary in the dome. The rate of flow could be measured by one of the manometers *K*.

By this arrangement, it was possible to keep the thickness of the oxide coat over the whole length of the crystal practically constant, since the factors determining the rate of reduction, temperature (very important), flow of hydrogen, and speed of the trough through the furnace could all be controlled. It soon became apparent that a perfect reduction is highly undesirable, because as soon as the last surface layer is gone, the surface tension of the liquid metal becomes so large that it coagulates into large drops and thus destroys entirely the uniform cross-section of the crystal. This effect made it necessary to provide an arrangement which permitted the production of a very thin oxide layer over the crystal. For this purpose, compressed air was used, which went first through the valve *J*, then through the stopcock *D* which opened the way to *C* either for the hydrogen or the air. For making the change between these two gases as fast as possible, every unnecessary apparatus-volume not exposed to the direct flow was avoided. Therefore, the hydrogen manometer, for instance, could be closed with the stopcock *L* as soon as the air-flow, which was measured by the manometer *K* (right), started.

For producing the "second generation," the rod was placed in the trough, as mentioned above, and the furnace heated to about 310°. To prevent coagulation, the first few millimeters were placed so that they did not melt, then the hydrogen flow was turned on at a pressure of 20–25 mm water-column and the motor started. Thus the metal rod melted into the shape of the trough and was reduced so that the surface became very bright. As soon as the other end of the rod entered the furnace the hydrogen-flow was stopped and the air-flow started to cover this part with an almost invisible coat which fixed the shape of the end of the rod and thus prevented the metal from running forward under the influence of surface tension.

This second generation was, in general, monocrystalline, but the orientation was at random. To predetermine the orientation the method of inoculation by a seed-crystal was used. For this purpose, the metal rod obtained by the previous methods was placed again in the trough, the latter being placed in the furnace, again under a flow of hydrogen, so as to melt the right end of the rod. The thin oxide-coat kept the end in shape, since the temperature (about 290°) of the furnace was so low that no appreciable reduction occurred. As soon as the end was liquid (Fig. 2a), the glass dome of *C*

was removed, a hooked steel needle was introduced and the oxide coat taken off the end of the liquid rod (Fig. 2b). The hydrogen flow prevented a re-oxidation of this point, whereas the oxide-hull of the rest kept the rod in shape. Then the seed-crystal, the end of which was cleaved immediately before using, was brought into the trough (Fig. 2c). The liquid end of *X* and the left end of *Y* were brought into contact very carefully, so that they united over a small region (Fig. 2d). Again coagulation had to be avoided by pulling the seed-crystal out a trifle so as to produce a little constriction between *X* and *Y*. (Fig. 2e). The glass dome of *C* was then replaced, the tube itself pushed back into the furnace for annealing the transition (Fig. 2f) and the hydrogen-flow was replaced by an air-flow. This process was necessary in order to protect the very delicate junction between *X* and *Y* by a uniform oxide coat (see later). After the rod and the seed-crystal reached

Fig. 2. Method of inoculating rod with seed crystal.

thermal equilibrium, corresponding to the new position in the furnace, the motor was started and thus the crystal started to grow. As soon as the junction came out of the furnace, the air flow was replaced by hydrogen to prevent a thickening of the oxide coat on *X*. It was found that this oxide coat had to be very thin, almost invisible to the eye, and had to be very uniform over the whole rod. For fulfilling this condition, it was necessary to start the hydrogen rather exactly at the moment at which the junction started to crystallize. The moment at which the air inside *C* was replaced by hydrogen could easily be observed on account of the difference of viscosity of the two gases. The storage pressure of the hydrogen indicated by the manometer *K* (left) was large as long as the rest of the air had to flow through the capillary of *C*, but went down to a constant value as soon as the tube contained only hydrogen. The opposite was the case if the hydrogen was replaced by air.

Thus the third generation of the crystal was obtained. After the whole rod crystallized, it was taken out of the trough very carefully and etched with diluted nitric acid. If all precautions had been observed carefully, the crystal obtained was perfectly uniform in shape and orientation, and not the smallest alien crystal could be observed. The orientation of the crystal was

Fig. 3. Crystal 1 shows first "generation" after removing the glass cover. It is polycrystalline and shows many regions of twinning. Crystal 2 is second "generation," its core being singly-crystalline. However, its surface contains many crystals in twin orientations due to oxide stress. Crystal 3 is third "generation" (X) with the seed-crystal (Y) in orientation P_1 . The rod is a single crystal.

exactly the one of the seed crystal, no matter which orientation that had. It was found also that this method had no limitations in the matters of the lengths and the cross-sections of the crystal. Fig. 3 shows a photograph of the first three generations of crystals.

As has been mentioned above, the whole investigation was undertaken to study the factors influencing the orientation and perfection of these

Fig. 4. Cross-section of arrangement for crystallization in a magnetic field.

crystals with special regard to the influence of a transverse magnetic field. The method just described allowed a very exact location of the zone in which the crystal formed. If the temperature of the furnace was high enough, this zone was outside the furnace; hence it was possible to bring it between the pole-pieces of an electromagnet M . The pole-pieces P were shaped so as to concentrate the field between two edges and thus across the crystal over a

length of 18 mm. This distance was necessary to allow for the unavoidable uncertainty in the exact position of the zone of formation. Fig. 4 shows an enlarged cross-section of the arrangement whereas Fig. 5 is a top view photograph which shows the crystal *C* lying in the trough *G* as it comes out of the furnace *F* and crystallizes between the pole pieces *P* of the magnet *M*.

This method has the disadvantage that the direction of the lines of force cannot be changed relative to the rod. Nevertheless, it is possible to change the orientation in the rod by inoculation with different seed crystals. This, allowed the study of the influence of the field at different angles with regard to the trigonal axis.

Fig. 5. Top view of the formation of the single crystal *C* carried in the trough *G* between the pole pieces *PP* of the magnet *M* after being molten in the furnace *F*.

MECHANICAL FACTORS INFLUENCING THE ORIENTATION AND PERFECTION OF CRYSTALS

For studying the kinds of influences preventing a perfect growth of Bicrystals, about 500 crystals were grown under circumstances which were changed systematically. The results concerning the disturbances involved in the artificial growth by inoculation can be summarized as follows.

Two different kinds of mischief in the production of single crystals have to be separated, (a) the fact that the rod consists of several crystals with different orientations, and (b) the fact that the inoculation of the rod by a seed-crystal does not succeed. All experiments were performed at a constant speed (exact to about 0.2 percent), in absence of vibration, and at a constant temperature (exact to 2°).

The failure of an inoculation can consist of

- (1) That the orientation of the rod has no relation whatsoever to the seed crystal;
- (2) That the orientation of the rod is partly the same as the seed crystal;
- (3) That the orientation of the rod is the twin orientation of the seed crystal.

The first case occurred in general if the contact between rod and crystal was bad. It was quite remarkable how an almost invisible layer of oxide between both parts destroyed entirely the influence of the seed crystal,

although they may have congealed and formed a unit after solidification. Case (2) can have the same cause as (1). If the face of contact between both parts was partly contaminated by oxide, then one half grew in the orientation of the seed crystal, whereas the other half, separated from the seed by contamination, formed one or several new centers of crystallization which produced new crystals which grew together with the inoculated one. There may be still another cause which will be discussed later. The most interesting case is (3). Here one can have a perfect crystal, the orientation of which is the same throughout, only that the perfect cleavage of the seed plane is replaced by one of the imperfect cleavage planes. The same effect may occur in case (2), where one can obtain the parallel growth of two crystals with interchanged planes.

It is well known that almost any deformation in a Bi crystal results in the production of twin-lamellae^{3,4} where the (111) plane is replaced by one of

Fig. 6.

Fig. 7.

Twin lamellae caused by distortion in Bi single crystals. The illumination under the microscope was such as to show the original orientation of the crystal dark (Fig. 7) or bright (Fig. 6). The white line in Fig. 7 corresponds to 1 mm.

the (11 $\bar{1}$) type. The change takes very little energy because the rhombohedral symmetry of Bi is almost a cubic one. Fig. 6 and Fig. 7 illustrate this effect on two artificially distorted crystals of Bi, which show the appearance of the twin lamellae differently illuminated. Thus the conclusion is easily reached that the twinning occurred in case (3) at the point where seed and rod came in contact. A close investigation of this effect brought out the following facts.

If the seed-crystal is not perfect, i. e. if it contains twin lamellae which are easily observed under the microscope after etching (3) the rod will grow frequently in the twin orientation. It is furthermore very hard to avoid the twinning effect if one cleaves crystals in special orientations, as was shown by x-ray diagrams, but it is possible by careful handling to extend the twinned region not farther than a few tenths of a mm beyond the cleaved plane. Thus

³ P. Mügge, *Jahrbuch d. Mineralogie* 1, 183 (1886).

⁴ A. Goetz, *Proc. Nat. Acad.* in press.

in order to inoculate the rod with an undisturbed seed, it is only necessary to bring the trough, after the contact between rod and seed is made (Fig. 2 e) far enough into the furnace so that the imperfect end of the seed is melted (Fig. 2 f). Then the unhurt part of the seed reinoculates its imperfect part and the rod starts to crystallize in the desired orientation.

However, it was very surprising that case (3) occurred very often, even though this precaution was taken, i.e. the rod crystallized in the twin orientation in spite of a perfect seed.

Closer investigation showed that this effect had two reasons. One should expect that if one inoculates with well twinned seed crystals i.e. where distinct regions of the crystal have either the normal or the twin orientation as shown in Fig. 6 and 7, one would obtain rods of both orientations depending on the position of the point up to which the seed was melted. But it was discovered that *the rod grows in an orientation possessed by a region of the seed which was already molten*. This process is shown schematically in Fig. 8 where X is the molten rod and Y the seed crystal having the twin-lamellae $t, t \dots$. In case the seed Y was molten up to point 1, X grew in the orientation corresponding to the seed. If Y was molten up to point 2, X grew in the twin orientation.

Fig. 8.

tation. But if Y was liquidified up to point 3, where the twin lamella was doubtlessly melted, X grew still in the twin orientation. This experiment could be repeated as often as desired. The maximum distance still effective between the border of the lamella and the end of the molten region was, in general, several millimeters. Fig. 9 shows an enlarged photograph of the transition between seed and rod. The illumination of the crystal is such as to show the parts of the desired orientation bright. The dark crystal is the seed (right) which shows three good intersections of twin lamellae. The white half to the left is the beginning of the inoculated rod, which shows the same orientation as the twin lamellae of the seed-crystal. The sharp transition shows how far the seed was melted. The original end of the seed had one twin lamella which was melted about 0.5 mm beyond its left border, but was still able to determine the orientation of the rod. The faint black lines on the left crystal are twin lamellae in the rod which were produced later to show that they have the original orientation of the seed indicated by their dark appearance.

This phenomenon shows that the forces determining the orientation of a crystal are not destroyed at the melting point and exist within the liquid as long as the temperature is near to that of the melting point.

The study of the conditions of successful inoculation with untwinned crystals (or seeds melted far beyond the limits of the imperfections) revealed

another phenomenon which points in the same direction. As mentioned above it was necessary (to preserve the perfect shape of the rod) to pull the seed a little away from the rod (Fig. 2 d) so that the junction was constricted (Fig. 2 e). It goes without saying that this constriction concerned only the region where the metal was molten entirely. It was found, nevertheless, in almost all cases, that the rod grew in the twin orientation of the seed if the crystallization was started from the position of the trough in Fig. 2 e. After the crystal was finished, it was etched and the region where the twin orientation occurred could be determined easily. It started always close to point 1 (Fig. 4 e) i.e. at the beginning of the constriction, no matter whether the melted region of the seed reached still farther or not.

The only way to avoid this twinning effect in the liquid was to anneal the liquid junction at temperatures much higher than the melting point; hence the

Fig. 9. Seed crystal with twin lamellae (right), inoculated crystal (left) grew in twin orientation although the twinned region of the seed was molten. The white line corresponds to 1 mm.

trough had to be backed into the furnace (Fig. 2 f) and kept in that position for 5-7 minutes before the crystallization was started.

This effect shows that within the temperature region of the "liquid crystal," the twinning occurs just as well as in the solid state with the only difference that the little energy necessary for changing the shape of the liquid rod (determined by its surface tension and the shape of the thin oxide cover) is already sufficient to produce the effect.

The fact that the orientation of a crystal is not destroyed immediately after melting could be shown in another experiment. If a polycrystalline rod (first generation) was put into the trough and was run through the furnace with the usual speed, but a maximum temperature which was only slightly above the melting point, a polycrystalline rod was obtained which had the same position and the same orientation of the different prominent crystal elements as it had before it entered the furnace although it had been molten and recrystallized. As soon as the temperature was higher, an entirely different polycrystalline combination occurred.

The high sensitivity to any stress applied to the transition between solid and liquid metal causes another effect which is highly undesirable. If a single crystal rod which is covered by oxide was placed in the trough and pulled through the furnace, a rod was generally obtained which was monocrystalline at the core but polycrystalline at the surface, an observation which was also made by Kapitza². Under the microscope, it was observed that the alien crystals have the shape of thin stripes running along the rod, each of them starting at a wrinkle in the oxide coat produced by the shrinking of the metal at the moment of melting. As soon as the rod crystallized, these wrinkles were stretched out again, but the pressure necessary for this process was sufficient to cause twinning if the oxide coat was sufficiently thick. The alien crystals produced by this cause were only at the surface and could be removed by etching. The effect was different if the rod was free from oxide and the oxide coat was produced around the rod in the molten state. Then the whole hull was too small for the solid form and it had to be split by the solidifying metal, which caused pressures which were very often able to start an entirely new orientation. Hence it was necessary to grow the metal in a reducing atmosphere so that the oxide coat was too thin to affect the structure of the crystal, but sufficient to preserve the shape of the molten rod.

With regard to the orientation which is produced by these stresses, the following can be said: Any tension longitudinal with regard to the rod results in an orientation in which the trigonal axis is normal to the rod. If the original orientation is already such, the tension has no influence at all. If the stresses are not very large, the new orientation is obtained by twinning which places the trigonal axis in a direction in which the energy needed for overcoming the obstacles of thermal contraction is smaller. This is the reason as already stated in another paper,¹ crystals, the trigonal axes of which are parallel to the rods, are very difficult to obtain with the usual methods, which apply either longitudinal tensions or lateral compressions to the zone of formation due to the expansion of the metal at the moment of crystallization. The method described avoids these influences and allows the growth of all possible orientations equally well. However, the opposite effect can be shown, where a longitudinal compression prevents the perfect growth of a crystal, the axis of which is normal to the rod. If a rod was covered with a heavy oxide coat and inoculated with a seed, the axis of which was normal to the rod, the last end of the rod had an orientation in which the axis became more parallel to the rod. The obvious reason is that the oxide at the end of the rod formed a kind of sack, the end of which prevented the longitudinal expansion and thus exerted a longitudinal compression, which resulted in an orientation of maximum contraction parallel to it.

THE INFLUENCE OF THE MAGNETIC FIELD UPON THE CRYSTALLIZATION.

Since the orientation and perfection of these crystals could be influenced mechanically when in the molten state, it seemed worth while to study whether or not a magnetic field applied to the zone of formation would produce any effects.

The way in which the magnetic field was applied has already been described. The tests were made as follows: The crystal (third generation), with an already definite orientation, was put into the trough and the tube pulled back into the furnace so far that the left end of the crystal did not melt. The temperature of the furnace was increased so much that the transition between liquid and solid crystal was approximately at the middle of the pole pieces when the crystal reached its thermal equilibrium, a process which took in general, 5 minutes. Then the magnetic field was excited and the driving mechanism started at the same time. Thus the molten part of the rod crystallized again within a transversal magnetic field of a strength of 20,000-21,000 gauss.

It is obvious that there are three different possible orientations of the crystal with respect to the rod, or to the direction of the lines of force. These orientations which differ fundamentally are as sketched in Fig. 10. This

Fig. 10.

shows the trough G (dotted) with the crystal, the latter cut parallel to its main cleavage plane. These three main orientations are:

Name	Trigonal axis to field		(111) plane to field	
	rod	field	rod	field
P_1	\perp	\perp	\parallel	\parallel
P_2	\perp	\parallel	\perp	\perp
P_3	\parallel	\perp	\perp	\parallel

As long as the conditions of growth were not influenced accidentally, *no influence of the magnetic field upon the crystallographic orientation could be observed, no matter which of the above main orientations was introduced into the field.* It is to be mentioned however, that this result can only be obtained if one succeeds in avoiding any secondary influence. Any shock, for instance caused by the sudden excitation of the magnet, transferred to the trough or to the furnace will immediately produce a change in orientation.

Moreover, crystals, the orientation of which had not been predetermined, were grown in a magnetic field to find out whether there exists an influence of the field on the first originating center of crystallization. In fact, indications were found which point toward a preference of an approximate parallelism of the trigonal axis and the lines of force. However, these results seem not to be precise enough for a definite statement, since first the number of measured crystals produced this way was not large enough that the results could be considered statistically; and second, it is known that the direction of the

heat-gradient with relation to the rod can predetermine the orientation aside from any mechanical influence. Thus, the non-inoculated crystal may not have been entirely free to grow in any orientation because the apparatus did not allow a change of the direction of the heat-gradient with respect to the rod. On the other hand, it is certain that these predetermining influences are extremely small because they cannot affect, in any way, the growth of an inoculated crystal. However, the influence of the applied field showed itself to be smaller than the orienting forces of an inoculating crystal and may be similar in magnitude to the orienting forces of the gradient, which makes it possible that the effects produced by the latter fog the former.

DISCUSSION

The results obtained by the above observations may be able to explain a number of experiences of other authors. It has been already suggested in a previous paper¹ that the extended experiments of Hoyem and Tyndall⁵ on single zinc crystals may find their explanations in the effect of the stress applied to the zone of formation by the weight of the liquid column hanging from the crystal. The variation of the successfulness of an inoculation with the temperature of the molten metal can thus be explained, because the length of the liquid column depends upon that temperature and herewith its weight.

Moreover the lack of success of several methods of Kapitza² and his explanation thereof is confirmed and becomes understandable as soon as one realizes that in the case of liquid bismuth, the interchange of the main cleavage plane with an $(11\bar{1})$ plane is exactly the effect which occurs in any plastic deformation of solid bismuth. It seems that there are only two alternate interpretations possible: First, one could assume that the twinning force of the crystal becomes infinitely small in the neighborhood of the melting point so that the smallest strain, as given, for instance, by the surface tension of the liquid metal, is sufficient to start the twinning; or second, in view of the observed facts one might assume that the twinning effect occurs within the melted region, which would mean that the crystal is not destroyed entirely after melting, but that it consists still of units which preserve their orienting power. The first makes it impossible to explain the fact that qualities can be "inherited" by a growing crystal from the molten region of a seed crystal or to explain the preservation of a polycrystalline structure in a bar heated above the melting point. These units exist apparently only over a small range of temperature, since the phenomena through which one infers their presence disappear entirely about 10° above the melting point (annealing of the liquid metal).

One is perhaps not entirely wrong in assuming that these units are of the same nature as the "blocks" in a Bi-crystal described by the author in a recent paper⁴ in connection with the theoretical considerations of Zwicky.⁶ In this case, one considers that the melting crystal disintegrates first into its

⁵ A. G. Hoyem and E. P. T. Tyndall, *Phys. Rev.* **33**, 81 (1929).

⁶ F. Zwicky, *Proc. Nat. Acad.* **15**, 253, 000 (1929).

blocks which exist within a state of equilibrium of dissociation with the liquid metal at each temperature. This "block phase," however, exists only over a small range of temperature.

There are several indications in experiments of other authors which are in favor of this hypothesis. Boydston⁷ found in observing the thermal e.m.f. of Bi-crystals of different orientations that the e.m.f.'s characteristic for the crystalline state did not disappear exactly at the melting point, but continued for a few degrees. Thus (to quote his own words) "it appears, in fact, as if some crystalline arrangement still persists in the molten metal . . ."

Futhermore, Traube and vonBehren have shown⁸ that the dissolving of a crystal into an almost saturated solution results in separating particles of ultra-microscopic size from the crystal, "submicrons," which exist for a considerable length of time. The parallelism between the melting process and the process of dissolving into a saturated solution does not need to be mentioned.

Finally, it is possible to connect the observations by Stewart and his collaborators⁹ concerning the "cybotactic" state of matter with these results. It seems as if there is no principal difference between the "block-phase" and the "cybotaxis."

Regarding the extremely small energy needed for influencing the orientation in a liquid crystal, I was surprised to find no orientating effect caused by the magnetic field on a crystal with a predetermined orientation. This however, does not contradict necessarily, experiments which were performed by Plücker¹⁰ and Leduc.¹¹ From experiments on polycrystalline Bi solidified in a magnetic field, Plücker finds that among the individual crystals, one direction is predominant, that is where the trigonal axis is parallel to the lines of force. A result of this kind should be expected, if there is any positive effect, because of the anisotropic diamagnetism of Bi, as the trigonal axis is known to be parallel to the most "paramagnetic" direction. The observations of Leduc¹¹ point in the same direction. He crystallized Bi in spherical glass containers which could be suspended within a field of 4-5000 Gauss. These Bi balls were polycrystalline without doubt, but suspended in the field they turned into a direction in which the "average main axis" of the conglomerate was parallel to the lines of force. If the ball was formed outside the field, no prediction about its zero position in the field could be made, but as soon as the sphere had crystallized within the field, the zero position was the same as its position during crystallization. The explanation of this effect is obviously the same as of Plücker's observations, although, the orientation of the conglomerate was not measured by Leduc.

It seems surprising that Welo did not find any effect of this kind in a recent study.¹² It may be due to the fact that his way of casting his disk in a

mould with good thermal conductivity produced a polycrystallization so rapid that the orienting effect was very small.

Our own observations make a directional effect, in a crystal which crystallizes completely in a magnetic field, probable with a sign which agrees with Plücker's and Leduc's experiments. They show, however, that this effect is so small that it cannot overcome the orienting forces of a seed-crystal.

The presence of the magnetic effect shows furthermore, that the orientation of a crystal must exist already in the liquid state provided that the crystal unit has still freedom to move with regard to the rod. This supports again the existence of the above "block-phase." The insensibility of the inoculated crystal shows further that the growing crystal, if under stable conditions, must have an already ordered section of the liquid ahead of it. Then the orienting effect of a magnetic field is too small to break up the liquid arrangement.

Nevertheless, it was found that the magnetic field influences considerably other properties of a Bi crystal formed in it, as stated already by the author and his collaborators^{13, 14, 15}. More extensive results will be published soon.

I feel very much indebted to Dr. R. A. Millikan for the interest he showed in this investigation, and I should like to express my thanks to my assistants, Mr. M. F. Hasler and Mr. A. B. Focke for their very helpful assistance.

LETTERS TO THE EDITOR

Prompt publication of brief reports of important discoveries in physics may be secured by addressing them to this department. Closing dates for this department are, for the first issue of the month, the twenty-eighth of the preceding month; for the second issue, the thirteenth of the month. The Board of Editors does not hold itself responsible for the opinions expressed by the correspondents.

Hyperfine Structure in the Spectra of Neutral Manganese

A light source, designed by Schüler, operated at liquid air temperatures in conjunction with a prism spectrograph and silvered Fabry-Perot etalons is being used to study the hyperfine structures in the spectral lines of neutral manganese. At 4000Å a resolving power of approximately one million is obtained. The observed fine-structure patterns although identical in appearance with those found in praseodymium (Phys. Rev. **34**, 1397, 1929) are in general a fifth to a tenth as wide. Patterns of from 2 to 6 components are found, some degrading toward the red and others toward the violet. For example, $\lambda 4030$ has the fine-structure components,

Int.	10	9	8	7
$\Delta\lambda$	0	+0.0122	+0.0230	+0.0317
$\Delta\nu$	0	-0.0751	-0.1416	-0.1951
			6	5
			+0.0379	+0.0420
			-0.2333	-0.2585

degrading toward longer wave-lengths while $\lambda 4018$ has the

Int.	10	9	8	7
$\Delta\lambda$	0	-0.0152	-0.0274	-0.0377
$\Delta\nu$	0	+0.0941	+0.1696	+0.2333
			6	5
			-0.0456	-0.0516
			+0.2822	+0.3193

components degrading toward the violet. Since the well-known gross structure of Mn I and II in general shows strictly *LS* coupling, an excellent opportunity for the study of the role played by *s*, *p*, and *d* electrons in producing hyperfine structure presents itself. The $^6S_{5/2}$ ($3d^5 4s^2$) term is apparently quite narrow. With a nuclear angular momentum $(5/2)(h/2\pi)$ for Mn, the $^6P_{43}$, $^6P_{33}$ ($3d^5 4s 4p$) and the $^6D_{43}$ ($3d^5 4s$) terms are each broken into six *normal* components with

separations 0.116, 0.107, 0.082, 0.068, 0.052 and 0.075, 0.066, 0.054, 0.038, 0.025, and 0.099, 0.086, 0.069, 0.054, 0.040 cm^{-1} respectively. While the $^6P_{43,33,23}$ terms each have six components, the $^6D_{43,33,23,13,12}$ and $^6P_{33,23,13}$ terms have 6, 6, 6, 4, 2 and 6, 6, 4 components respectively, as would be expected with $i=2\frac{1}{2}$. The total fine-structure separation 0.348 cm^{-1} for $^6D_{43}$ ($3d^5 4s$) is due chiefly to the 4s electron, the 3d electrons contributing very little. To this the 4p electron contribution is (a) added to give the $^6P_{43}$ ($3d^5 4s 4p$) separation 0.414 cm^{-1} and (b) subtracted to give the $^6P_{33}$ ($3d^5 4s 4p$) separation 0.258 cm^{-1} .

The total separations of the fine structures for the three terms $^6D_{43,33,23}$ are found to be proportional to the $\cos si$, when $J \geq i$ and $\cos Ji=1$, as predicted. The fine structures that have as yet been photographed are found to be in excellent agreement with the "Theoretical Interpretation of Hyperfine Structure" given by one of the authors (H. E. W. in a Letter to the Editor, Phys. Rev. **34**, 1288, (1929)). The value of i for manganese appears to be $(5/2)(h/2\pi)$ as is also the case for lanthanum and praseodymium. The ratio between gross-structure and fine-structure is about 20,000:1 the same order of magnitude as the ratio between the mass of a manganese atom and five times the mass of an electron. This indicates that if the nuclear spin is due to negative charges, as seems to be the case from the *normal* order of the fine structure, they must carry with them the total mass of the nucleus in space quantization.

The Unified Field-Theory and Schwarzschild's Solution

Vallarta¹ has investigated, with negative results, the consistency of Einstein's unified field-theory with the generalized relativity theory of 1916 as regards the gravitational equations in a spherically symmetrical field. It appears, however, that he made a slip toward the beginning of his calculation. The expressions for the potentials should be

$$\phi_i = 2Ax_i - \frac{W'x_i}{Wr} \quad (i=1, 2, 3)$$

instead of simply the first term. As a result, Vallarta's expressions for $V_{\beta\gamma}^\alpha$ and $V^{\alpha\beta\gamma}$ are wrong. When the necessary corrections are applied, Vallarta's gravitational equations

$$\frac{\partial V^{\alpha\beta\gamma}}{\partial x_\gamma} + V^{\sigma\beta\gamma}\Gamma_{\gamma\sigma}^\alpha + V^{\alpha\sigma\gamma}\Gamma_{\sigma\gamma}^\beta + V^{\alpha\beta\sigma}\Gamma_{\sigma\gamma}^\gamma = 0 \quad (1)$$

yield, for the case $\alpha=\beta=4$

$$dU/dr = U/r - U^2/r$$

where U is the square-root of the coefficient of dr^2 in the fundamental quadratic differential form. The solution of this differential equation,

$$U = \frac{1}{1 - (m/r)},$$

where m is a constant, is identical with Schwarzschild's solution for the coefficient itself. The agreement extends, therefore, as far as the first power of m/r .

For the cases $\alpha=\beta=i$ ($i=1, 2, 3$), one of the consequences to be deduced from (1) is the differential equation

$$W(U-1) - rW' = 0$$

where W is the square-root of the coefficient of dt^2 in the fundamental quadratic form. This is satisfied, though, of course, not uniquely, by a function identical with Schwarzschild's solution for the coefficient itself:

$$W = 1 - (m/r),$$

the approximation being of the same order as in the case of U . It must be borne in mind however, that the implications of (1) have by no means been exhausted.

It would indeed be surprising, in view of the basic similarity between Vallarta's and Schwarzschild's metrical assumptions, and in view also of the relation between Einstein's theories of 1916 and 1929, were results wholly at variance with Schwarzschild's solution obtainable from Vallarta's problem.

Limiting Resolving Power of a Crystal Grating

From time to time one sees in the literature reports of unsuccessful attempts to find certain fine structures in x-ray spectral lines. These attempts are generally made by the single crystal photographic method, but the following considerations apply to other spectrometers, either single or double crystal type.

The resolution is limited by the "tolerance" angle of the crystal. This "tolerance" angle, namely, possible deviations from Bragg's Law, is determined by the parallel crystal method on the double spectrometer. The crystals used by Davis and Purks (Proc. Nat. Acad. Sci. Feb. 1928) in analyzing the structure of the $\text{MoK}\alpha_1$ line gave a rocking curve of 6 seconds at half-maximum, at first order. The corresponding width at second order would be 2" of arc. The tolerance angle of one of these crystals was $6/2^{1/2} = 4''$, at first order and $2/2^{1/2} = 1.4''$ at second order.

The Bragg law of crystal reflection is $\lambda = 2d \sin \theta$, so $d\lambda = 2d \cos \theta d\theta$. The fine structure displacement is represented by $d\lambda$. In the case of the $\text{MoK}\alpha_1$ fine structure the observed displacement was 0.085 x.u. This gives the angular displacement $d\theta = 3$ seconds of arc. This deviation is less than the tolerance angle of the best crystal at first order and of course the structure would be entirely washed out. Such fine structure is beyond the power of a single crystal analysis, no matter how great the distance between slits or the distance of the photographic plate.

The above applies also to double crystal analysis. Unless the tolerance angle at any order is less than the fine structure displacement, the structure will not be observed.

The width of rocking curve given here is for fine calcite. The corresponding curve for good rock-salt is 600 seconds (Davis and

Stempel, Phys. Rev. May, 1922). Rock-salt is of course not suited to fine structure work.

In general no crystal should be used for fine structure observation until its tolerance angle has been determined. Many specimens of calcite give quite wide rocking

curves and are unsuited to this type of experiment.

The Third Law of Thermodynamics

R. H. Fowler admits the practical utility of the concept of absolute entropy but maintains that no theoretical significance is to be attached to the concept. This viewpoint seems at variance with the one in vogue at the present time in physics.

If we treat absolute entropy as an operational concept the only question that needs to be considered in connection with the Third Law, is whether it is ever necessary to assume the entropy of the pure stable crystalline form of a substance different from zero at 0°K in order to calculate the correct value of the entropy from the thermal data. Difficulties might be anticipated in the case of elements in which the atoms have j values different from zero where it might prove necessary to add a term $R \ln (2j+1)$ to the value obtained from the thermal data. In the case of the sodium atom (Rodebush, Proc. Nat. Acad. 13, 185 (1927)) and the oxygen molecule (Giauque and Johnstone, Jour. Am. Chem. Soc. 51, 2300 (1929)) it has been shown that the thermal data alone lead to the correct value, so that apparently no correction factors are likely to be needed for electronic moments.

In the case of nuclear spins the situation is otherwise. Here theoretically the thermal data alone should still give the correct value of the entropy but practically only in the case of hydrogen (Rodebush, Proc. Nat. Acad. 15, 678 (1929)) can the correct value of the en-

trophy be obtained in the customary manner. For all hydrogen compounds we shall presumably have to add arbitrarily the quantity $R \ln 2$ per gram atom of hydrogen to the thermal entropy. In the case of other elements having nuclear spins the term $R \ln (2s+1)$ may be omitted from the entropy of elements and compounds alike for all thermodynamical calculations.

It is not to be doubted that in the case of an element such as sodium which has a nuclear spin of several half units, that a heat effect due to the change in orientation of the nuclear spins will appear at low temperatures, but the heat effect will be so small and the temperature so low that it will probably elude observation, although the corresponding entropy change is, of course, not negligible. The more or less prevalent idea that no appreciable entropy changes occur at very low temperatures is evidently not justified.

The only other case that needs to be noticed is that of elements which are isotopic mixtures. If we consider the separation of isotopes as a process which is realizable thermodynamically then we shall have to consider the isotopic mixture as a solution and solutions together with supercooled liquids are unstable forms of matter at 0°K and the Third Law does not apply to them.

Note on Hartree's Method

Hartree's method of self-consistent fields, for determining atomic models, has seemed to many persons to stand rather apart from the main current of quantum theory; in spite of the papers of Gaunt and the writer, showing its connection with Schrödinger's equation, it has seemed to contain arbitrary and empirical elements. It appears, however, that it has a very close relation to the variation method. That principle states that, if one has an approximate wave function con-

taining arbitrary parameters or arbitrary functions, one will have the best approximation to a solution of Schrödinger's equation if one chooses the parameters or functions so that the energy is stationary with respect to slight variations of them. Suppose one sets up an approximate wave function for a general problem of the motion of electrons among stationary nuclei, by assuming a product of functions of the various electrons: $u = u_1(x_1) \cdots u_n(x_n)$; suppose further that

one apply the variation principle by varying separately each of the functions u_i , leaving the others constant. The n variation equations so obtained prove to be those for the motion of the n electrons, each in a separate electrostatic field; and the field for each electron is obtained by adding the densities u_i^2 for all the other electrons, and finding by electrostatics the field of this charge and of the nuclei. Thus this field is self-consistent in the sense of Hartree; the result is a generalization of his method to more complicated problems than atomic ones.

For atoms, Hartree's procedure differs in the one detail that instead of taking the field so obtained (which would not be quite spherically symmetrical), he averages over all directions, to get a real central field for each electron to move in. This process also can be partly, although not entirely, justified by variation methods. If one demands that the functions u_i be solutions of a central field problem—that is, that they be products of spherical harmonics of the angles, by functions of r —and vary only the function of r , then one finds that the potential should be averaged over all orientations; but with a certain weighting function, not used by Hartree, depending on the spherical harmonic occurring in the wave function of the electron for which we are finding the potential. That is, Hartree's method could be slightly changed in this matter, with slight improvement of the results; but, except for this, it is definitely the best method, in the sense of variation principle, using central fields.

Closer examination shows that the potential we have found differs from Hartree's merely in being slightly dependent on the m , as

well as the n and l , of the electron one considers. As a result, the energy levels of the different electrons of the same n and l , but different m , will differ slightly, an effect without physical meaning. In an earlier paper of the writer (Phys. Rev. **32**, 343, 1928), it is shown that essentially this same dependence on m results in only a small error, and further, that this effect has a very close connection with the resonance terms, and that by considering these also, the energy again becomes independent of m . It would therefore not be sensible to make this slight improvement in Hartree's method without at the same time making the more important one of considering resonance. If one wished to do this, one could again use variation methods, to derive a new method similar to self-consistent fields: one would demand that the wave function be written not as $u_1(x_1) \cdots u_n(x_n)$, but as a linear combination of such functions with permuted indices, so arranged as to have proper symmetry relations; and one would then vary the u_i 's to make the energy a minimum. This would give a method similar to Hartree's, but really an improvement on it. Some preliminary calculations by Drs. Zener and Guillemin indicate that it may really be feasible to carry through this improvement. Their method differs from that sketched here only in that they represent the u_i 's by simple analytic forms containing parameters, which they vary, instead of determining them by numerical solutions of a differential equation.

An X-Ray Study of Molecular Orientation in the Kerr Effect

Perhaps the most successful theory of the Kerr effect for liquids is that which assumes a tendency toward definite orientation of the molecules under the influence of an electric field. Such a tendency towards uniform orientation should affect the x-ray diffraction pattern of the liquid by increasing the intensity of the x-rays observed at the peak of the diffraction curve. It is the purpose of this experiment to investigate the existence of such an effect.

Since, in observing the Kerr effect, the light beam is at right angles to the applied field it was thought best to arrange the path of the

x-ray beam as nearly at right angles to the applied field as possible. In order to accomplish this the following method was devised. The liquids used were placed in a cylindrical glass cell one end of which was covered by a thin window of cellophane on whose inner side thin aluminum leaf was fastened. A beam of unfiltered x-rays from a molybdenum tube operated at 35 K.V. was reflected from this face, the cell replacing the crystal of an ordinary Bragg spectrometer. Measurements of the intensity of the reflected beam were made in the ordinary manner used in crystalline reflection, namely by turning the cell through

an angle θ , and the ionization chamber through 2θ , where θ is the grazing angle of incidence on the cell. The intensity of the reflected x-rays from an empty cell was less than 15 percent of the intensity observed at the same angle when the cell was filled. Soller slit sets were used to collimate both the incident and reflected beams. The reflection curves obtained for benzene and nitrobenzene were found to be practically the same as the corresponding liquid diffraction curves obtained by other methods.

The Kerr effect is most strongly shown by nitrobenzene when a rapid succession of practically instantaneous sparks are passed through it. Since full-wave rectification was used in obtaining the high potential for the x-ray tube it was thought desirable to synchronize the electric impulses across the cell with the peaks of the x-ray pulses. This was done by connecting a water rheostat in parallel with the tube, and connecting the aluminum leaf of the cell to this rheostat. In order to sharpen the electric impulse across the cell a spark gap was inserted between the rheostat and the cell, and a jet of air was blown between the balls of this gap. The other end of this cell was covered with a grounded brass plate.

All observations of the effect of the electric field were made with the cell at the grazing angle corresponding to maximum reflected intensity. Readings were taken alternately with and without a field of 13 K.V. per cm across the cell. Four groups of readings of 25 pairs each were obtained for nitrobenzene, the increases in intensity being 1.8, 2.5, 2.1, and 2.9 percent respectively for each of the four groups. The average increase with the field was thus found to be 2.3 percent, with a probable error of 0.5 percent. The effect thus

observed is between four and five times the probable error.

With a field applied to the cell in the manner described above benzene shows little or no Kerr effect. Hence, if the Kerr effect is due to partial molecular alignment, benzene—under the field applied to nitrobenzene—would not be expected to show a change in intensity of the peak maximum. Four groups of readings of 25 pairs each, taken alternately with and without the field in precisely the same manner as nitrobenzene, showed for benzene changes in intensity of -0.4 , $+0.3$, -0.3 , and -0.6 percent. The negative sign is used to indicate the variations in the opposite direction to that of nitrobenzene. The average change in intensity for all readings is -0.3 percent which is well within the probable error. This lack of any definite shift in intensity with the field rules out the possibility that the effect observed for nitrobenzene might be due to a slight bending of the cellophane window as a result of electrostatic forces of attraction.

The results here given show for nitrobenzene an increase in intensity of the peak maximum of an amount that is approximately five times the probable error, while for benzene any change observed lies not only well within the probable error but also is, for the most part, in a direction opposite to that of nitrobenzene. It would thus seem that for nitrobenzene there occurs, when the proper type of electric field is present, a small but detectable tendency of the molecules to align themselves in a common direction.

A Comparison of the Reflection Spectra of $\text{SmCl}_3 \cdot 6\text{H}_2\text{O}$ at Room Temperature and at that of Liquid Air with its Absorption Spectra at Low Temperatures

In a communication to Nature¹ we discussed a change which we observed in the absorption spectrum of a single crystal of $\text{SmCl}_3 \cdot 6\text{H}_2\text{O}$ as we lowered the temperature to that of liquid hydrogen. Many lines or bands which were prominent in the spectrum at room temperature practically disappeared at the temperature of liquid hydrogen and

others which were extremely faint increased in intensity as the temperature was lowered. We ascribed this change in relative intensity to the presence of different electronic configurations of Sm^{+++} in the solid state in thermal equilibrium. (This interpretation is in accord with the magnetic behavior of Sm^{+++} .)

¹Freed and Spedding, *Nature*, April 6 1929).

At present we wish to report the most general features of the reflection spectra

obtained by reflecting a continuous spectrum from the surfaces of many small crystals of the same salt. The reflected spectrum has the characteristics of an absorption spectrum. The lines which we attribute to the electronic modification stable at the low temperature, that is those which are prominent only at the low temperatures in absorption are found relatively much more intense at room temperature in reflection. In addition, the lines in the reflection spectra are accompanied by satellites about 160 cm^{-1} toward the red. The reflection spectrum at room temperature also contains narrow diffuse bands which were not observed in absorption.

At the temperature of liquid air, these bands sharpen and become resolved into multiplets consisting of very narrow lines. At this temperature, many new lines make their appearance and they tend to cluster on both sides of the lines which are found in the absorption spectrum. Satellites accompany the prominent lines at intervals of about 160 cm^{-1} at the temperature of liquid air also.

Our method of photographing the reflection spectra does not exclude the simultaneous appearance of the absorption spectrum. (We intend to eliminate this spectrum in our future work.) However, the astonishing intensification of the "low temperature" lines in the reflection spectrum at room temperature cannot be ascribed to any spurious experimental influence because we are considering relative intensities only.

A fluorescence or an unusual reflecting power appears to take place on the violet side of a number of the lines in the reflection spectrum at the temperature of liquid air which do not occur in absorption.

The force fields in the surface are definitely different from those within the crystal. It is conceivable that in the surface there is a higher concentration of the "low temperature modification" than corresponds to an equilibrium distribution within the crystal. It is also possible that the absorption coefficient of this particular modification may be greater under these conditions.

The large number of entirely new lines which occur in the reflection spectrum may possibly be due to the fact that the electrostatic fields to which the Sm^{+++} ions within the crystal are exposed are no longer regular in direction and in magnitude in the surface so that any "forbidden" electronic jumps within the crystal are no longer "forbidden" in the surface. In other words, the probability of transition between certain states has been increased. We are investigating this phenomenon further.

An Observed Periodicity in the Packing Fraction

It is found that a single oscillatory curve can be fitted to the packing fraction data taken by Aston, eliminating the necessity of the two branches at the small mass number end (Proc. Roy. Soc. **A115**, 487 (1927)). Points of maxima are located at mass numbers 6, 10, 13, 17, 21, 25, \dots , and minima are found for the elements whose mass number is an integral multiple of four.

The mass number of the atom was assumed to be given by the expression $4n+x$, where $n=0, 1, 2, 3, \dots$ and $x=1, 2, 3$ or 4. Since the packing fraction represents an average mass defect per proton it is evident that in the $4n+1$ type of atom, the one proton is loosely connected to the core of the nucleus probably existing as a satellite in the form of a neutron. In the $4n+2$ type the two protons

are a little more tightly bound to the core. Similarly for the $4n+3$ atom. And finally for the $4n+4$ type of atom we find maximum packing, the four protons probably forming an alpha-particle which goes into the center of the nucleus. These conclusions were arrived at after a calculation of the change in packing fraction per proton produced by the "x" portion of the atom had been made wherever possible. Curves were plotted showing the effect of the value of "x" on this change in the packing fraction, these being used to determine the points of maxima and minima.

The fact that the packing becomes greater for the $4n+4$ atoms with an increase in mass number indicates that the alpha-particle actually goes into the center of the nucleus each time "x" becomes equal to four. This

was suggested by Aston. This continues up to about mass number eighty. A definite oscillation for the kryptons is observed. For the heavier elements the data are not accurate enough to show any oscillation if it is present. Aston has attributed the general rise in the curve beyond mass number eighty to the increasing complexity of the nuclear structure. If this oscillation continues for the heavier elements, we might still have the alpha-particle forming in the nucleus as before but instead of going into the center they begin to form satellites around the now

"filled up" center of the nucleus. For the heaviest elements these satellites may be far enough from the core to render them unstable and thus produce atomic disintegration with the ejection of alpha-particles and electrons. More accurate packing fraction data are needed to determine definitely whether this periodicity exists for the heavy elements.

The Unified Field Equations and Schwarzschild's Solution. II.

All of the implications of Eq. (1) of the previous note¹ have since been worked out. Another consequence of the case $\alpha = \beta$ ($\alpha, \beta = 1, 2, 3$) is

$$\frac{W''}{UW} + \frac{W'}{Wr} \left(\frac{2}{U} + \frac{1}{U^2} - \frac{U'r}{U^2} - 1 \right) - \frac{U'}{U^2r} + \frac{1-U}{U^2r^2} = 0. \quad (1)$$

The only other non-trivial case so far not considered is $\alpha \neq \beta$ ($\alpha, \beta = 1, 2, 3$); this yields

$$\frac{W''}{UW} + \frac{W'}{Wr} \left(\frac{2}{U} - \frac{2}{U^2} - \frac{U'r}{U^2} - 1 \right) - \frac{U'}{U^2r} - \frac{2(1-U)}{U^2r^2} = 0. \quad (2)$$

If for U is substituted the solution obtained in the previous note

$$U = 1/(1-m/r),$$

both (1) and (2) are seen to have as a particular solution

$$W = C \left(1 - \frac{m}{r} \right), \quad (3)$$

where C is a constant. On subtracting (2) from (1) and reducing, we get

$$W'r = W(U-1) = \frac{mW}{r-m} \quad (4)$$

which was found in the previous note as a consequence of the case $\alpha = \beta$ ($\alpha, \beta \neq 4$). The general solution of (4) is (3); and if the reasonable boundary condition

$$\lim_{r \rightarrow \infty} W = 1$$

is applied—the corresponding condition is already satisfied by $U=$, the constant C becomes unity, and we find, unambiguously,

$$W = 1 - \frac{m}{r}.$$

On the Vibration Frequencies of HCl and HBr in the Liquid State

Modified scattering of the mercury 4047 line by HCl in the liquid has already been reported (Science, March 29, 1929). We have repeated our measurements with greater accuracy and have also measured a modified line from liquid HBr, at -75°C . Calling ν_1 the observed modified line, ν_0 the molecular frequency and λ_0 the corresponding wavelength, the results are (reduced to vacuum):—

Liquid	ν_1	ν_0	λ_0
HCl	21924	2781	3.595 μ
HBr	22226	2479	4.033 μ

The value of ν_0 for gaseous HCl is 2886 (Wood, Phil. Mag. 7, 744 (1929); Colby, Phys. Rev. 24 (1), 53 (1929)), and for gaseous HBr is 2559 (Imes, Astrophys. J. 50, 251 (1919)). Comparing these with the above values, we see that ν_0 is shifted to the smaller frequencies in the liquid, 105 wave-numbers in the case of HCl and 80 in the case of HBr.

The Lorentz-Lorenz theory affords an explanation of frequency differences of a molecule in different physical states (see e.g. Wolf and Herzfeld, Handbuch der Physik).

Thus, letting ν_0' refer to the liquid, there is the relation

$$\nu_0' = \left(\nu_0^2 - \alpha \frac{Ne^2p}{m} \right)^{1/2}$$

where N is the number of molecules per unit volume in the liquid, p the number of resonating particles of charge e and mass m in a molecule, and α times the polarization per unit volume is the Lorentz force, α being $4\pi/3$ for a spherical cavity. But α when calculated from the above observed frequencies in the gas and in the liquid comes out not around $4\pi/3$ but 0.20 for HCl and 0.16 for HBr. In fact, using $4\pi/3$ for α makes the last term larger than ν_0^2 for these molecules.

However, this calculation is made with

The Reflecting Powers of Atoms for X-rays of Different Wave-lengths

In the course of measurements of atomic F -curves¹ experiments have been made to find out whether the scattering power of an atom changes with the wave-length of the x-rays used. It might be expected that such a wave-length effect, if it exists, would be most conspicuous in the neighborhood of characteristic frequencies of the diffracting atom. With this in mind, the F -curves of NiO have been mapped for molybdenum, copper and nickel radiation and points have been determined upon the curves of the metals iron, copper and nickel for molybdenum, copper, nickel and iron rays. This has been done by comparing the relative intensities of powder lines from these substances with the intensity of a standard NaCl reflection. Though the scattering powers thus obtained are not necessarily correct in absolute value, nevertheless as long as the F of the standard NaCl reflection is either constant or changes in a regular fashion with increasing wave-length, the relationships they show amongst themselves will be significant.

Earlier measurements from this laboratory² have shown that the scatterings of metallic iron and copper for copper K -radiation are less than for the $K\alpha$ line of molybdenum. Additional observations have shown (1) that the scattering power of a particular atom decreases with increasing wave-length as this wave-length approaches a critical excitation value for the scatterer; (2) that F is a minimum for this longest exciting radiation;

4.77×10^{-10} e.s.u. for e , that is, it assumes that the vibrating atom is H^+ . But we know that HCl and HBr do not have this structure. Dennison has, indeed, introduced into band spectrum theory the "effective charge," which he finds for HCl to be $0.199 \times 4.77 \times 10^{-10}$ e.s.u. (Phys. Rev. **31**, 503 (1928)). Using this value for e , and retaining $\alpha = 4\pi/3$, we now calculate $\lambda_0' = 3.578\mu$, in quite good agreement with our measured 3.595μ .

These results and others will be presented at greater length later.

E. O. SALANT
A. SANDOW

Physics Department,
Washington Square College,
New York University,
January 13, 1930.

(3) that this number then rises to a maximum for a wave-length equal to that characteristic of the scatterer; and (4) that thereafter it appears to fall slowly with further increase in wave-length. Thus, for example, the approximate values of Table I are obtained assuming $F(220, \text{NaCl}) = 15.62$.

TABLE I.

Wave-length	Fe $F(110)$	Ni $F(200)$	NiO $F(220)$	Cu $F(220)$
Mo $K\alpha$	15.87*	—	18.28	14.28*
Cu $K\alpha$	11.48	13.70	15.83	11.53
Ni $K\alpha$	9.77	14.48	16.88	11.18
Fe $K\alpha$	13.45	—	—	—

* See footnote 2.

The absorption coefficients of the diffracting powders enter into these determinations. The sequence of Table I is obtained, however, whether either experimental coefficients are used or those calculated by the general formula of Jönsson.³

The usual theory of the intensity of reflection from ideally imperfect crystals, to

¹ C. G. Darwin, Phil. Mag. **43**, 800 (1922); etc.; A. H. Compton, X-rays and Electrons (New York, 1926) Chap. V.

² A. H. Armstrong, Phys. Rev. **34**, 931 (1929).

³ E. Jönsson, Uppsala Univers. Årsskrift, 1928.

which these data are legitimately referable indicates that F , the ratio of the scattering of an atom to that of a single electron, may be expected to be constant for constant values of $\sin \theta/\lambda$. In other words, it will be the same for a particular reflection no matter what wave-length is employed.

The observed departures from this constancy probably have more than one cause. Thus the minimum in F which occurs at the critical absorption wave-length of the scattering atom is most naturally accounted for if energy which otherwise would be coherently scattered is utilized in the production of the secondary radiation. At the same time, the fact that maxima in F are always obtained at characteristic wave-lengths of the scatterer suggests some sort of resonance. Such

resonance, if it exists, cannot be sharp, however, for F falls away only slowly with longer wave-lengths.

It is apparent that photographs of RbBr made by Mark and Szilard⁴ with strontium and bromine radiations are expressions of variations in F of the same nature as those just described.

Detailed results of these experiments will be published soon.

THE PHYSICAL REVIEW

THE CAPTURE OF ELECTRONS BY ALPHA-PARTICLES

BY ARTHUR H. BARNES

PHYSICS LABORATORIES, COLUMBIA UNIVERSITY

(Received December 24, 1929)

ABSTRACT

A stream of electrons is superposed upon a beam of alpha-particles. The alpha-particles are then deflected by a magnetic field and counted by the scintillation method. Alpha-particles which have captured electrons will not be deflected to the point where observation is made, and consequently, the decrease in scintillations will indicate the number of captures which occur.

Probability of capture as function of relative velocity.—It is found that electrons are captured when their velocity equals that of the alpha-particle, and also, at a series of discrete velocities both greater and less than that of the alpha-particle. Counting scintillations due to singly charged particles showed that at certain of these discrete velocities one electron is captured. At the other velocities two electrons are captured. This was determined by counting scintillations due to neutral particles which had passed undeflected through the magnetic field. Both single and double capture occur at zero relative velocity, the latter predominating as the electron density is increased.

Calculation of the kinetic energy of the electron with respect to the alpha-particle corresponding to each of the velocities at which single capture occurs, gives a series of energy values which can be associated with the energy levels in the ionized helium atom. Similarly, for the case of double capture, the sum of the kinetic energies due to each of the two electrons, corresponds to the energy of the quantum states of both the parhelium and orthohelium types of atom. There is indication that the hitherto unobserved ground state of orthohelium is being formed. The conclusion is reached that in order for capture to occur, it is necessary that the electron, due to some external field, possess a kinetic energy, which, with respect to the nucleus, is either zero, or equal to the energy of one of the quantum states of the atom. In the latter case double the normal energy must be radiated, and the question arises as to whether it is radiated as two quanta of normal frequency, or as one quantum of twice that frequency.

There is evidence that the *penetrating power* of the singly charged and neutral particles is less than that of the nucleus alone.

Time required for capture of electron by alpha-particle.—The construction of one of the tubes used permitted the time during which the alpha-particle was in the electron stream to be made less than 3×10^{-10} sec without appreciably decreasing the percent of capture. The electron density under these conditions was of the order of 10^7 electrons per cc.

IN A previous report¹ an experiment was described which showed that an electron is captured by an alpha-particle only at definite relative velocities.

¹ Bergen Davis and A. H. Barnes, Phys. Rev. 34, 152 (July 1, 1929).

The series of energy values associated with these velocities was shown to correspond to the energy levels in the ionized helium atom.

The present paper gives the details of the experiment (which were omitted in the preliminary announcement) and presents additional information obtained with a new experimental arrangement.

FIRST EXPERIMENTAL TUBE

Two experimental tubes were constructed. The first tube is shown diagrammatically in Figure 1. The alpha-particle source is polonium deposited upon a pointed copper rod placed at *S*. A thin glass window *W*, 0.0005 cm thick, allows the alpha-particles to enter the tube. By thus placing the radioactive source outside the tube, contamination difficulties were entirely avoided.

After passing through the tube, the alpha-particles leave it by means of another window placed at *Y*, or if a sufficient magnetic field be applied at *M*, they will be deflected and pass out through a window at *Z*. The latter windows are each 0.001 cm thick. Zinc sulphide screens are placed outside the windows. Aluminum foil 0.0004 cm thick was placed before each screen to shield it from the light of the filament. The air is exhausted from the spaces between screen and window and also from the space between source and window.

Fig. 1. Diagram of first experimental tube. *S*, radioactive source; *W*, thin glass window; *F*, filament; *G*, grid; *R*, lead to silvered surface; *A*, second anode; *M*, magnetic field; *C*, copper seals; *Y*, and *Z*, zinc sulphide screens.

The source of the electrons is a large oxide-coated filament *F*, 2.5 cm square and made slightly concave. A hole 0.5 cm in diameter allows the alpha-particles to pass through. The current necessary to heat the filament was about 150 amperes and entered the tube through water-cooled copper seals at *C*.

The first anode *G*, is placed one cm from the filament and takes the form of a conical spiral of 60 mil tungsten wire. The diameter of the inner and outer turn is 0.4 cm and 2.5 cm respectively. The spacing between turns is 0.4 cm. The second anode *A*, is a nickle cylinder 0.5 cm in diameter and 3 cm long. It is placed 18 cm behind the grid *G*.

The inside of the glass vessel is silvered and the conducting layer grounded to prevent accumulation of charge on the walls. All metal parts were out-gassed in a vacuum furnace before being placed in the tube. The tube was evacuated, baked, and sealed off.

Electrons leaving the filament are accelerated to any desired velocity by the potential impressed upon the grid G . Due to the shape of the grid and filament, those electrons which pass through the grid will converge and proceed along the axis of the tube towards the anode A . The alpha-particle does not enter into a region of relatively great electron density until it reaches the point of convergence of the electron stream. If an electron is captured at this point, the alpha-particle will arrive at the magnetic field with a decreased charge, and consequently will not be deflected to the lower screen at Z . The decrease in scintillations observed at Z will therefore determine the number of captures which occur.

PROCEDURE AND RESULTS

The procedure followed with this tube was to vary the magnetic field until the alpha-particles were deflected to the lower screen Z . The potential applied to the grid G , and cylinder C , was then varied in small steps and the corresponding change in the number of alpha-particles arriving at Z was determined. During most of the runs the current to G was 60 milliamperes and to A , 0.08 milliamperes.

Fig. 2. Electron capture as a function of accelerating voltage.

It was found that capture takes place when the velocity of the electron is equal to that of the alpha-particle also at a series of definite electron velocities both greater and less than that of the alpha-particle. A curve showing the relation between capture and applied voltage as obtained with this tube is given in Figure 2. It consists of a double series of sharp maxima grouped on each side of a central peak. The velocity of the electrons corresponding to the voltage at which the central peak occurs is 1.44×10^9 cm/sec. This agrees closely with the calculated velocity of the alpha-particle after passing through the window of the tube.

If v is the velocity of an electron and u the velocity of an alpha-particle, then the kinetic energy of the electron with respect to the alpha-particle will be,

$$W = \left(\frac{1}{2}\right)m(v-u)^2$$

where m is the mass of the electron.

Let V_n and V_0 be the potential differences through which electrons must fall to acquire the velocities v , and u , respectively, then,

$$eV_n = mv^2/2$$

and,

$$v = (2eV_n/m)^{1/2}$$

similarly,

$$u = (2eV_0/m)^{1/2}$$

substituting,

$$W = \left(\frac{1}{2}\right)m \left(\frac{2e}{m}V_n - \frac{4e}{m}V_n^{1/2}V_0^{1/2} + \frac{2e}{m}V_0 \right) \\ = e(V_n^{1/2} - V_0^{1/2})^2$$

or,

$$\frac{W}{e} = (V_n^{1/2} - V_0^{1/2})^2 = E_n$$

where E_n is the energy expressed in volts when V_n and V_0 are in volts.

If in this equation we substitute for V_0 the voltage which will accelerate an electron to a velocity equal to that of the alpha-particle, and for V_n successively the voltages at which the observed peaks occur, then we arrive at a series of energy values which correspond to the energy levels in the ionized helium atom.

Table I gives the voltages of the observed peaks and the corresponding values of E_n . The last column gives the values of E_n as calculated from Bohr theory. There are of course two sets of observed values for E_n corresponding to the two cases in which $V_n > V_0$ and $V_n < V_0$.

TABLE I. Values of E_n for which capture takes place.

n	$V_n < V_0$	E_n	$V_n > V_0$	E_n	Mean of E_n	$E_n = 54.16/n^2$
1	295	50.6	1005	54.9	52.0	54.16
2	410	16.7	800	15.6	16.2	13.54
3	483	5.33	720	6.45	5.67	6.01
4	505	3.29	700	4.71	4.00	3.38
5	519	2.28	681	3.27	2.77	2.16
6	531	1.56	667	2.41	1.98	1.50
7	535	1.34	653	1.59	1.46	1.10
8	538	1.19	645	1.23	1.21	.84
9			638	.96		.67
10			635	.88		.54

It thus appears that the probability that an alpha-particle will capture an electron is great only when the kinetic energy of the electron with respect to the alpha-particle is either zero, or equal to the energy of one of the quantum states of the ionized helium atom. It is to be noted that the kinetic energy here referred to is that due to the applied field only.

The effect of varying the potential of the second anode A , with respect to the first G , was investigated. It was found that if the potential of A was made greater or less than that of G , then to maintain the condition for capture, it was also necessary to change the potential of G . Thus if the potential of A is decreased, then to maintain capture, it is necessary to increase the

potential of *G*. Another result of making the potential of *A* different from that of *G* is a considerable broadening of the peaks, especially when *A* is at a higher potential than *G*. These effects indicate that capture is taking place at some point between the first and second anodes, and that the velocity of the electrons is the governing factor.

It will be noticed that the peaks do not continue to the central peak as they might be expected to do, but stop abruptly at about the tenth energy level. It was thought that this might be due to re-ionization caused by collisions with the molecules of residual gas in the tube. This effect was investigated with the second tube and will be discussed later.

An alpha-particle which has picked up one electron will be deflected to the lower screen *Z*, when the magnetic field is doubled. If it has picked up two electrons it will pass through the magnetic field without deflection and arrive at the upper screen *Y*. It should therefore be possible to observe an increase in scintillations corresponding to every decrease.

When this procedure was tried no increase could be detected. It was further found that with the magnetic field entirely removed, a decrease in scintillations on the upper screen occurred at the same voltages at which decreases had formerly occurred on the lower screen. This effect indicated that the penetrating power of a singly charged or neutral particle was less than that of the nucleus alone.

Fig. 3. Diagram of second experimental tube. *S*, radioactive source; *W*, thin glass window; *A*, filament-anode system; *M*, magnetic field; *Z*, zinc sulphide screen.

SECOND EXPERIMENTAL TUBE

The second tube was constructed with four objects in view.

1. The reduction of the time of passage of an alpha-particle through the electron stream to a known small value.
2. The detection of scintillations due a singly charged and neutral particles.
3. The investigation of the effect of varying the velocity of the alpha-particle.
4. The investigation of the captureless intervals located on each side of the central peak.

The construction of the second tube is shown diagrammatically in Figure 3 and Figure 4. The electron source is an oxide-coated filament *F*, in the form of a flat disk with a 0.4 cm diameter hole at its center to allow the passage of the alpha-particles. Two mm in front of the filament is placed a plate *P*, with

0.5 cm diameter hole exactly opposite the hole in the filament. A 60 mil tungsten wire *T*, extends for one cm along the axis of the tube to a point within one mm of the plate *P*. Surrounding the wire is a cylinder *C*, 0.5 cm in diameter and 0.5 cm long. A second cylinder *D*, 2 cm in diameter and 10 cm long is placed 1 cm behind the first cylinder and on the same axis. The whole assembly is held rigidly in place and mutually insulated. Separate leads are brought out from each of the elements.

Zinc sulphide is placed on the inside of the flattened end of the tube at *Z*. The window used to admit the alpha-particles was of very nearly the same thickness (0.0005 cm) as that used on the first tube, so that the velocity of the alpha-particles in each tube was very nearly the same. The tube was evacuated and sealed off.

Fig. 4. Detail of filament-anode system in second tube. *F*, filament; *P*, plate; *T*, wire; *C*, cylinder; *D*, cylinder.

If the anode assembly (*P*, *C*, *D*, and *T*) is all put at the same potential the electrons leaving the filament will be accelerated by the field between the filament and the plate *P*, and wire *T*. Some will pass between this wire and the cylinder *C*, and so on to the larger cylinder at *D*. If however, the cylinder *C*, is put at filament potential, the field existing between *C* and *T* will be sufficient to deflect all the electrons which pass *P*, to the wire *T* near its end. The length of path which the electrons can possibly travel is thus limited. Furthermore every electron which reaches the wire *T*, must cross the paths of the alpha-particles.

PROCEDURE AND RESULTS WITH SECOND TUBE

The effect on capture of various arrangements of the anode system was tried. The plate *P*, wire *T*, and cylinders *C*, and *D*, were put at the same potential and the percent of capture determined. The cylinders *C* and *D*, were then put at filament potential and it was found that the percent of capture remained practically unchanged.

Under the latter conditions the greatest length of path possible for the electrons was approximately 5 mm, and since the velocity of the alpha-particle as it passes through this region is 1.45×10^9 cm/sec it follows that the process of capture must take place in less than 3×10^{-10} sec.

In the second tube the scintillations due to both singly charged and neutral particles could be detected. It was possible to count the increase in scintillations due to alpha-particles which had captured one electron and therefore struck the screen at a point midway between the center and the edge. It was also discovered that at certain voltages neutral particles were produced. They, of course, were not deflected by the magnetic field and struck the center of the screen.

Fig. 5. Double electron capture as a function of accelerating voltage.

It was found by observing at the center of the screen that there exists a whole series of voltages at which double capture occurs. A curve showing the relation between this type of capture and the applied voltage is given in Figure 5. There exists also an independent series of values at which single capture occurs, (Figure 6.). With the first tube it was not possible to separate

Fig. 6. Single electron capture as a function of accelerating voltage.

these two types of capture, (since only a decrease in scintillations could be observed) and consequently some of the peaks which were thought due to single electron capture were in reality due to double capture. The peak found at 410 volts for example was at first attributed to single capture. The second tube showed however, that this was a voltage at which double capture occurred, and that the single capture peak was at 418 volts.

The most striking feature of the curves is the narrowness of the peaks. This indicates that capture takes place at a point where the electrons are moving with a very uniform speed and direction. The electron velocity at this point will in general be somewhat less than that corresponding to anode potential. The observed voltage across the tube will therefore not indicate the true velocity at the point of capture. This condition introduces an error in the determination of the location of the peaks and consequently also in the calculated energy values. It should be possible to design an arrangement in which the electron velocity at the point of capture was very exactly known and so obtain correct values for the energy levels.

The whole range of voltage was investigated and the single capture peaks separated from those due to double capture. A revised table showing single capture voltages and the corresponding energy values is given in Table II.

TABLE II. Values of E_n for single capture.

n	$V_n < V_0$	E_n	$V_n > V_0$	E_n	Mean of E_n	$E_n = 54.16/n^2$
1	293	51.8	1005	54.9	53.3	54.16
2	418	14.8	800	15.6	15.2	13.54
3	481	5.53	719	6.45	5.99	6.01
4	508	3.16	700	4.71	3.93	3.38
5	519	2.31	689	3.72	3.01	2.16
6	531	1.56	673	2.69	2.12	1.50
7	535	1.39	662	2.02	1.70	1.10
8	540	1.12	652	1.51	1.31	.84
9	—	—	645	1.21	—	.67
10	—	—	637	.53	—	.54

Applying the energy relation given above to the case of the double capture peaks it is possible to calculate the kinetic energy of each electron with respect to the alpha-particle. If double capture takes place under conditions similar to that for single-capture, then the sum of the kinetic energies of each of the two electrons, (as acquired from the applied field, but with respect to the alpha-particle) should correspond to the energy of one of the quantum states of the helium atom.

Table III shows the voltages at which double capture occurs and the corresponding relative kinetic energy of one and of two electrons.

TABLE III. Values of E_n for double capture.

$V_n < V_0$	E_n	$2E_n$	$V_n > V_0$	E_n	$2E_n$	Mean of $2E_n$
315	43.0	86.0	955	43.5	87.0	86.5
327	38.6	77.2	930	38.4	76.8	77.0
338	35.4	70.8	921	36.0	72.0	71.4
347	32.1	64.2	907	33.6	67.2	65.7
360	28.4	56.8	885	29.7	59.4	58.1
375	25.0	50.0	848	24.1	48.2	49.1
395	19.5	39.0	815	18.0	36.0	37.5
410	16.4	32.8	803	16.4	32.8	32.8
428	13.0	26.0	783	13.5	27.0	26.5
448	10.5	21.0	760	10.8	21.6	21.3
460	8.25	16.5	738	8.2	16.4	16.5
486	4.60	9.20	708	5.3	10.6	9.90
507	3.24	6.48	672	2.60	5.20	5.84
533	1.49	2.98	661	1.96	3.96	3.47
537	1.25	2.50	652	1.51	3.02	2.76

The second value (77 volts) given in the last column of the table agrees with the observed total energy of the parhelium type of atom ($54.2 + 24.5$ volts). It is suggested that the first value, 86.5 volts, may correspond to the ground state of orthohelium, a configuration hitherto unobserved, but which might be formed under the special transition conditions peculiar to this experiment.

It is also probable that the remaining values constitute a double series, consisting of the energy levels of both the parhelium and orthohelium types.

No significance is to be attached to the fact that the peaks in Figures 2, 5, and 6, do not rise much above 50 percent. It was discovered after these curves had been taken that by a suitable adjustment of the position of the radioactive source it was possible to increase capture to over 90 percent.

Fig. 7. Typical peaks.

Two typical peaks taken under these conditions are shown in Figure 7. The peak at 719 volts is one due to single capture. The 738 volt peak is due to double capture.

The explanation of this dependence of capture on the position of the source is that the electron stream is not uniformly distributed over the area through which the alpha-particles are passing. Thus, if there is always a portion of the observed alpha-particles which pass through a region where the electron density is always too low for capture to occur, it will be impossible by merely increasing the current to the anode to make the percent of capture rise above a certain value. If however, the position of the source is so adjusted that all the alpha-particles which fall within the field of view of the microscope, (2.4 mm in diameter) must pass through the region of maximum electron density, then by increasing the current to the anode it is possible to make capture approach 100 percent.

The effect of gradually increasing the current to the anode T , when the voltage is held at one of the peak values is illustrated in Figure 8 and Figure

9. The curve in Figure 8 is taken at the single capture peak at 719 volts. Figure 9 is the curve obtained at the double capture peak occurring at 738 volts.

Fig. 8. Capture as a function of electron current. A curve taken at the 719 volt single capture peak.

Since these voltages are relatively close together, the electron density for a given anode current is probably not very different in each case, and there-

Fig. 9. Capture as a function of electron current. A curve taken at the 738 volt double capture peak.

fore the percentage of capture should be a rough indication of the relative probabilities of single and double capture.

Further information on this question is given in Figure 10 which shows a series of three curves taken at the 590 volt peak which corresponds to zero relative velocity of electron and alpha-particle. Curve (1) shows the manner in which the number of single captures varies with the current going to the anode *T*. It was obtained by counting increases in scintillations due to singly charged particles striking the screen at the midway point. Curve (2) shows the variation with current of the number of neutral particles which strike the screen at its center. Curve (3) shows the total decrease in scintillations as observed at the lower edge of the screen. The ordinates in this case are not given in percent but in the observed variation in scintillations per minute.

Fig. 10. Capture at zero relative velocity as a function of electron current. (1), single electron capture; (2), double electron capture; (3), total decrease of doubly charged alpha-particles.

For single capture, (Figure 8) saturation is reached when only 0.1 milliampere of current flows to the anode *T*. The order of magnitude of the electron density under these conditions is about 10^7 electrons per cc, which corresponds to an average distance between electrons of 4.6×10^{-3} cm. The process of capture must therefore involve some mechanism, which, when the energy condition is satisfied is effective over a relatively large region of space.

With the second tube it was possible to investigate the effect of reducing the velocity of the alpha-particles. Two different velocities were tried by interposing aluminum foil between the radioactive source and the window. The resultant velocities of the alpha-particles were 1.35×10^9 cm/sec and 1.21×10^9 cm/sec. The whole series of peaks was found to shift in each case. Several of the peaks were located in their new position and the corresponding energy levels calculated by means of the energy relation already given. A comparison of these values with the values found at the higher alpha-particle velocity showed very good agreement.

The intervals on each side of the central peak where no capture occurs were found to be much narrower with the second tube than with the first. Whereas with the first tube they were 40 volts wide, with the second they

were only about 22 volts wide. In other words capture terminated at the tenth energy level in the first tube and at about the fifteenth energy level in the second. If these captureless intervals were due to re-ionization by collision with the residual molecules of gas in the tube, then the width of the intervals should be dependent on the length of path between the point of capture in the electron stream and the magnetic field. To test this the magnet was placed in two positions along the tube at M , and at N , (Figure 3) such that the distance ($A - M$) was double the distance ($A - N$). It was impossible to detect any change in the width of the interval under these two conditions. These captureless intervals must therefore be due to some cause other than collisions of this kind.

CONCLUSION

In the type of recombination taking place in this experiment the electron does not fall from rest into a given energy level (except in the special case when the velocities of electron and alpha-particle are equal). It has an initial kinetic energy, due to the applied field, equal to that of the energy level at which it is captured. Twice the normal energy must therefore be radiated, and the question arises as to whether it is radiated as two quanta of normal frequency, or as one quantum of double that frequency.

The striking result of this experiment is the discovery that electron capture is governed by a definite energy condition. In order for capture to occur, it is necessary that the electron, due to some external field, possess a kinetic energy, which, with respect to the nucleus, is either zero, or equal to the energy of one of the quantum states of the atom.

It has been shown that electron capture takes place in less than 3×10^{-10} sec in a region where the electron density is probably not greater than 10^7 electrons per cc. Probably the time involved is actually much less than this. The process of capture must therefore involve some mechanism whose action is extremely rapid, and when the energy condition is satisfied, effective over a relatively great region of space. When the energy condition is not satisfied the capture mechanism either does not function at all, or operates in such a manner that the probability of capture is relatively very small. The inference to be drawn is that under certain energy conditions, the mutually effective radius of action of the electron and the nucleus may be relatively very great, while under other energy conditions it is very small.

The results of this experiment are based upon the counting of over 700,000 alpha-particle scintillations.

In conclusion, the writer wishes to express his appreciation and gratitude to Professor Bergen Davis for suggesting this research, and for his continued interest and encouragement throughout the course of the experiment. Many thanks are also due to the other members of the department of Physics.

THE RELATIVE INTENSITIES OF SUPER-MULTIPLYET LINES

BY JAMES H. BARTLETT, JR.
INSTITUT F. THEORETISCHE PHYSIK, LEIPZIG

(Received December 27, 1929)

ABSTRACT

A simple method is described by which one may construct wave functions for the case of (*jj*) coupling. The wave functions for $(2p)^2$, so determined, agree with those given in a previous paper, when one sets the electrostatic interaction equal to zero. It is shown how the ordinary multiplet intensity formulae may be modified to give the relative intensities in a super-multiplet for (*jj*) coupling. The modified formulae, applied to the transition $(2p)^2 \rightarrow 2p3s$, give relative intensities in agreement with those found in the above paper, for this limiting case. The sum-rules hold quite generally for non-equivalent electrons, and it is shown to what degree they hold for a transition such as $(2p)^2 \rightarrow 2p3s$.

ON THE basis of the Darwin-Pauli theory of the spinning electron it has been found possible^{1,2} to calculate the relative intensities of super-multiplet lines for certain transitions, such as $(ds \rightarrow fs)$ and $(2p\ 2p \rightarrow 2p\ 3s)$. The intensities so found are dependent upon the strength of the electrostatic interaction between the electrons, as compared with that of the magnetic interactions between spin and orbital angular momenta. In the limiting case of strong electrostatic interaction, or (*ls*) coupling, these intensities agree with those calculated from the formulae for relative intensities within an ordinary multiplet. In the other limiting case, that of (*jj*) coupling, where the spin-orbit interaction is predominant, analogous formulae can be set up and the intensities so obtained would agree with those found from more general formulae when the electrostatic interaction is set equal to zero. The difficulties involved in obtaining these general formulae for any degree of coupling have already been mentioned in a previous paper.² Accordingly, it seems expedient to calculate the theoretical intensities for the two limiting cases and to use some suitable method of interpolation when comparing with experiment.

1. THE WAVE FUNCTIONS AND ENERGY VALUE FOR (*jj*) COUPLING

For simplicity, we shall at first deal with only two electrons. For (*jj*) coupling, we are to consider as a perturbation the magnetic interaction between each electron and its own orbit. Each electron can be considered

¹ W. V. Houston, Phys. Rev. 33, 297 (1929).

² J. H. Bartlett Jr., Phys. Rev. 34, 1247 (1929). A sign error in the matrix components of the intercombination lines should be corrected. Both c_1 and c_8 should have the opposite sign. None of the conclusions of the paper are invalidated, to our degree of approximation. Furthermore, in the roots ϵ_3 and ϵ_4 , one should substitute +8 for -8.

separately during this perturbation calculation and then the product functions, or a linear combination thereof, will represent the total system. As usual, we group those functions together which have a common $m = \sum m_l + m_s$, where m_l and m_s refer to the projections of l and s , the azimuthal and spin quantum numbers, on a preferred axis. For an externally undisturbed system, terms with different m 's cannot combine, since m represents a constant of the motion. The wave functions are written

$$\psi_\alpha^m = R_{ln}(r) P_l^{m-1/2} S_\alpha; \quad \psi_\beta^m = R_{ln}(r) P_l^{m+1/2} S_\beta.$$

The two possible values of the spin variable are S_α and S_β respectively, and

$$P_l^{m_l} = (l - m_l)! \sin^{m_l} \theta \left(\frac{d}{d \cos \theta} \right)^{l+m_l} \frac{(-\sin^2 \theta)^l}{2^l l!} e^{i m_l \phi}.$$

Let

$$\gamma_{ln} = \frac{\hbar^2}{16\pi^2} \frac{Ze^2}{m_0^2 c^2} \int R_{ln}^2 \frac{1}{r^3} d\tau \quad \text{and} \quad \epsilon = \frac{\Delta E}{\gamma_{ln}}.$$

For the perturbation arising from the interaction between spin and orbit, the secular equation is:

$$\begin{vmatrix} m - \frac{1}{2} - \epsilon & (l - m + \frac{1}{2})^{1/2} (l + m + \frac{1}{2})^{1/2} \\ (l - m + \frac{1}{2})^{1/2} (l + m + \frac{1}{2})^{1/2} & -m - \frac{1}{2} - \epsilon \end{vmatrix} = 0.$$

The roots are $\epsilon_1 = l$ and $\epsilon_2 = -l - 1$, and the corresponding wave functions are:

$$\begin{aligned} \psi_1^m &= (1/2l+1)^{1/2} [(l+m+\frac{1}{2})^{1/2} \psi_\alpha^m + (l-m+\frac{1}{2})^{1/2} \psi_\beta^m] \\ \psi_2^m &= (1/2l+1)^{1/2} [-(l-m+\frac{1}{2})^{1/2} \psi_\alpha^m + (l+m+\frac{1}{2})^{1/2} \psi_\beta^m]. \end{aligned}$$

One sees that, for the state l , $j = m_{\max} = l + \frac{1}{2}$ and for the state 2, $j = m_{\max} = l - \frac{1}{2}$.

The calculation thus far deals with coupling of the type $(s_1 l_1) = j_1$. In order to treat coupling of the type $(j_1 j_2) = j$ one must construct antisymmetric wave functions from products of functions such as ψ_1^m and ψ_2^m . For instance, set³

$$\psi_{j_1 j_2}^m = \left(\frac{1}{2} \right)^{1/2} \begin{vmatrix} \psi_{j_1}^{m_1}(1) & \psi_{j_1}^{m_1}(2) \\ \psi_{j_2}^{m_2}(1) & \psi_{j_2}^{m_2}(2) \end{vmatrix}.$$

If now, for a given m , the vectors j_1 and j_2 combine to give only one j , then the state is not degenerate for (jj) coupling and will be represented, except perhaps for a sign factor, by a function of the above type. Just as frequently, however, one finds a degeneracy and the correct wave functions for a given value of j are found by taking linear combinations, the coefficients being

³ In the more general case of more than two electrons, the antisymmetric functions will have the determinant form. See J. C. Slater, Phys. Rev. (being published). The notation used above is similar to that of the paper to which reference is here made.

determined from a perturbation calculation, the electrostatic interaction between the electrons being the perturbation. This degeneracy is for a given set $(j_1 j_2)$ combining to give different j 's. If one should take the wave functions for the same j , as determined by this process, but for different sets $(j_1 j_2)$, and repeated the process, this would give the correct wave functions for (ls) coupling. This is to be expected, since it should make no difference in which order the various perturbations are applied. In the previous paper,² the reverse order was employed, and the results agree, both for energy values and for wave functions.

The total energy of the two-electron system for (jj) coupling is given by

$$E = E(n_1 l_1) + \gamma_{l_1 n_1} \epsilon(j_1) + E(n_2 l_2) + \gamma_{l_2 n_2} \epsilon(j_2).$$

This agrees with the work of Goudsmit⁴ if we make $\gamma = a/2$.

2. SELECTION RULES

Let us denote the set of quantum numbers $(nljm)$ by p . Then the matrix element for a transition involving two electrons will be a linear combination, in the zeroth approximation, of matrix elements of the type

$$z(p_1 p_2; p_3 p_4) \sim \delta(p_2 p_4) z(p_1 p_3) + \delta(p_1 p_3) z(p_2 p_4) - \delta(p_2 p_3) z(p_1 p_4) - \delta(p_1 p_4) z(p_2 p_3). \quad (1)$$

Thus, whether the coupling be of the (ls) (jj) type, as long as the wave functions are formed by the linear combinations of functions of the unperturbed system, then two-electron jumps are not permitted. This is true for any number of electrons, but only as a first approximation. According to Pauli's exclusion principle, no two electrons can have the same p and so, for any transition, we have only one term on the right-hand side of equation (1). Let this term be the first, i.e. $p_2 = p_4$. That is, for one of the two electrons, all four quantum numbers remain the same, and for the other, the ordinary selection rules hold. In the (jj) coupling case, therefore, j_1 can change by 0, ± 1 and j_2 does not change. If $p_1 = p_3$ instead, then $\Delta j_1 = 0$ and $\Delta j_2 = 0, \pm 1$.

3. INTENSITIES

Consider the transition $(n_1' l_1' j_1' m_1'; n_2 l_2 j_2 m_2) \rightarrow (n_1'' l_1'' j_1'' m_1''; n_2 l_2 j_2 m_2)$. The z -matrix will be a linear combination of a number of "unperturbed" z -matrices, which have the form $\int [R_{l_2 n_2}(2)]^2 r_2^2 dr_2 \int R_{l_1' n_1'}(1) R_{l_1'' n_1''}(1) r_1^2 dr_1 \int P_{l_1'}^*(1) z_1 P_{l_1''}(1) d\omega_1$ corresponding to the term $z(p_1 p_3)$ in Eq. (1). Thus, the radial integration gives a common factor and, since this is the only way in which the principal quantum numbers can enter, they have no influence on the relative intensities in a super-multiplet. It makes, therefore, no difference in the relative intensities as to whether the electrons are or are not equivalent. The equivalence is manifested, however, in the disappearance of certain states with the result that certain intensity sums are not proportional to statistical weights of the corresponding states.

⁴ S. Goudsmit, Phys. Rev. 31, 946 (1928).

For (jj) coupling, j_2 plays the same role as s , and j_1 the same role as l , respectively, in (ls) coupling. We can introduce a notation analogous to the Russell-Saunders notation, namely, $r(j_1)_j$, where $r=2j_2+1$. The j_1 labels the valence electron, and r is the multiplicity. Even when the two electrons are equivalent, there is no ambiguity as to which is the valence electron, unless $j_1=j_2$. In this case one must double the intensity as calculated from the formulae to be given, to allow for the two possibilities.

The ordinary multiplet formulae can now be rewritten in terms of j_1 and j_2 instead of l and s . In the ordinary multiplet theory the statistical weight of an $r(l)$ state is $r(l+1)$, e.g. a 3D state has a degeneracy of fifteen. For (jj) coupling, the statistical weight of an $r(j_1)$ state is $r(2j_1+1)$, except for equivalent electrons with $j_1=j_2$, where it becomes $2rj_1$. The degeneracy of a $ps\ ^4(1/2)$ state is eight, that for a $(2p)^2\ ^4(3/2)$ state is twelve, and that for a $(2p)^2\ ^4(1/2)$ the same as for $(2p)^2\ ^2(3/2)$, namely eight.

The formulae in terms of j_1 and j_2 follow:

$$\begin{aligned}\Delta j_1 = \pm 1 \quad J_{-1} &= G_j A_{j-1, j_1-1}^{j, j_1} = \frac{C}{4jj_1} P(j, j_1) P(j-1, j_1) \\ J_0 &= G_j A_{j, j_1-1}^{j, j_1} = \frac{C}{4jj_1} \frac{2j+1}{j+1} P(jj_1) Q(jj_1) \\ J_{+1} &= G_{j-1} A_j^{j-1, j_1} = \frac{C}{4jj_1} Q(jj_1) Q(j-1, j_1) \\ \Delta j_1 = 0 \quad J_0 &= G_j A_{j, j_1}^{j, j_1} = \frac{C}{4jj_1} \frac{2j+1}{j+1} \frac{2j_1+1}{j_1+1} R^2(j) \\ J \pm 1 &= G_j A_{j-1, j_1}^{j, j_1} = G_{j-1} A_j^{j-1, j_1} = \frac{C}{4jj_1} \frac{2j_1+1}{j_1+1} P(j, j_1) Q(j-1, j_1)\end{aligned}$$

where

$$\begin{aligned}P(j) &= (j+j_1)(j+j_1+1) - j_2(j_2+1) \\ -Q(j) &= (j-j_1)(j-j_1+1) - j_2(j_2+1) \\ R(j) &= j(j+1) + j_1(j_1+1) - j_2(j_2+1).\end{aligned}$$

The A 's are the squares of matrix elements. For any super-multiplet, or group of lines belonging to a transition such as $sp \rightarrow pp$, the value of C is the same for all lines. The sum of intensities from any state with equivalent electrons over all the states (with non-equivalent electrons) to which transitions can be made is, for a given super-multiplet, proportional to the statistical weight of the initial state. If these sums be taken horizontally, then in general the vertical sums will not be proportional to the corresponding statistical weights due to the exclusion of certain states which would be possible if the electrons were not equivalent.

As examples of applications of the formulae we give below the results (1) for a case with two non-equivalent electrons, and (2) for two equivalent electrons,

		j	1	2	1	0		
	$4(\frac{3}{2})$	0	$2 \cdot 2 = 4$	0	0	0	4	
		2	$2 \cdot 5 = 10$	$2 \cdot 5 = 10$	0	0	20	24
	$4(\frac{1}{2})$	2	5	5	0	0	10	16
		1	1	5	0	0	6	
	$2(\frac{3}{2})$	2	0	0	10	0	10	16
		1	0	0	2	4	6	
	$2(\frac{1}{2})$	0	0	0	$2 \cdot 2 = 4$	0	4	4
	Sums		20	20	16	4		
			40		20			

It is seen that the total intensity in a given system is proportional to the multiplicity of that system. For non-equivalent electrons both horizontal and vertical sums are proportional to the corresponding statistical weights, e.g. $4(1/2):4(3/2):6(1/2):6(3/2)=8:16:12:24$. For the equivalent electrons, the sums from the $(2p)^2$ states are likewise proportional to the statistical weights, e.g. $4(3/2):4(1/2):2(3/2):2(1/2)=12:8:8:2$.

However, this is not so for the sums from the $2p3s$ states, but would be true if the two p electrons were not equivalent. It should be noted that the $4(1/2)$ and $2(3/2)$ states of the $(2p)^2$ configuration have the same energy, but differ in the value of j which the valence electron has. (In the one case, $j_1=1/2, j_2=3/2$ and in the other case $j_1=3/2, j_2=1/2$ where j_1 denotes the

valence electron). The intensities given above for the transition $(2p)^2 \rightarrow 2p3s$ agree with those found from the general formulae of the previous paper,² when one sets the electrostatic interaction equal to zero.

As to the comparison with experiment, the observed intensities vary greatly from observer to observer, perhaps due to the excitation conditions. Furthermore, in some cases the identification of terms is in question. However, the intensities given by Mack⁵ for the super-multiplet $d^9p \rightarrow d^9s$ in Ge V and SnV are not in any marked disagreement with what one should expect from Table I. Where (jj) coupling is not realized, it may sometimes be possible to interpolate between this case and that of (ls) coupling. This question, as well as the allied ones of term-crossing and co-ordination to series limits, is beyond the scope of the present paper, but in all probability can be treated by obtaining the general formulae for a few simple cases and by then applying the method of induction. The calculations involved are not impossibly complicated for two electrons.

In conclusion, I wish to thank Professor Slater for helpful suggestions, and Harvard University for the renewal of my Parker Travelling Fellowship.

AN EXTENSION OF THE SPECTRUM OF Tl II

BY STANLEY SMITH

DEPARTMENT OF PHYSICS, UNIVERSITY OF ALBERTA

(Received December 12, 1929)

ABSTRACT

The spectrum of singly ionized thallium has been obtained by using the metal in a hollow cathode discharge in helium. Spectrograms have been made from 1900Å. to 8000Å. The newly found terms here reported are $6s8d^3D_{1,2,3}$, $6s8d^1D_2$, $6s9s^3S_1$, $6s10s^3S_1$, $6s6f^3F_{2,3,4}$, $6s7f^3F$ and an unclassified term $2s^0$. Absolute term values have been calculated from the sequence $6s6d^3D_2$, $6s7d^3D_2$, $6s8d^3D_2$. The ionization potential is found to be 20.30 volts. Tables of term values and of about sixty newly classified lines are given. Fourteen new multiplets arising from the fine structure of the terms are also tabulated.

1. INTRODUCTION

THE spectrum of singly ionized thallium has been investigated by Rao, Narayan, and Rao,¹ by McLennan, McLay, and Crawford² and by Smith.^{3,4} A further publication by McLennan, McLay and Crawford⁵ has not only extended the number of known terms but has also revealed the fine structure character of some of the terms. A very interesting feature of the fine structure of the Tl II terms was found to be the relatively large values of the differences between the term components as compared with those previously found by Back and Goudsmit⁶ for Bi I and by Jackson⁷ for Cs I. McLennan, McLay and Crawford were able to account for the observed structure of the Tl II lines by assuming that the nucleus has a spin of quantum number $\frac{1}{2}$, as Jackson had previously found to be the case for the nucleus of Cs I.

The further progress in the elucidation of the Tl II spectrum which is here reported, has been made by examining the spectrum obtained from a hollow cathode discharge in helium.

2. EXPERIMENTAL

As the Schüller lamp and the experimental details of its use have been previously described by Schüller,⁸ Paschen⁹ and Sawyer¹⁰ it is not necessary to enter into any detailed account of the apparatus. There is, however,

in the carbon at the closed end and a semi-circular carbon stop was inserted in the open end to correspond with the remaining piece of carbon at the other end, so that when the electrode was put into the tube with its axis horizontal and the thallium was melted, the carbon acted as a trough to hold some of the molten metal. On replacing the electrode the cleaning process with the oxygen discharge was continued, care being taken to prevent the thallium from melting. The tube was then pumped out to a hard vacuum and the

helium made to circulate through the apparatus. A heavy discharge was then passed through the tube until the thallium became molten, when half the metal ran out on to the outside aluminum electrode leaving the carbon cylinder half full of thallium with an untarnished surface.

A potential difference of about 1500 volts was applied to the electrodes by means of a variable voltage transformer in series with a rectifying valve. The spectrum from 1900Å to 8000Å was photographed by means of a two meter grating arranged on a Rowland mounting and giving a dispersion of about 8.5Å per mm in the first order. A Hilger interchangeable spectrograph was also used with quartz and glass trains. Neither of these instruments, although the best at the disposal of the writer, gives sufficiently large dispersion or high resolution for an accurate investigation of the fine structure. Consequently the fine structure separations measured are, at the best, only accurate to about one-half of a unit of wave-number.

3. RESULTS

The newly found terms are $6s8d^3D_{1,2,3}$, $6s8d^1D_2$, $6s9s^3S_1$, $6s6f^3F_{2,3,4}$, $6s7f^3F$, an unclassified term here denoted by 2_3^0 and $6s10s^3S_1$. The last mentioned term is given tentatively as only the $6s7p^3P_{0,1,2}$ - $6s10s^3S_1$ combinations have as yet been found.

The term values given in Table I are arrived at by taking $6s^2S_0$ to be 164,600, a value which makes the Rydberg denominators of the three $6snd^3D_2$ terms vary in much the same way as do the corresponding terms of Hg I. The ionization potential of singly ionized thallium would then appear to be 20.30 volts.

The tabulated term values in the case of terms for which the fine structure differences have been measured are the averages of the term values of the two components, the fine structure intervals being listed on the right hand side of the table. To make the table as complete as possible all the previously found terms and fine structure intervals are also included.

Reference might be made to the abnormal nature of the $6s6f^3F$ terms. It will be noticed that the partial inversion of the terms differs from that of the $6s5f^3F$ terms. Written in the order of descending magnitude the 5 F terms are F_3 , F_2 , F_4 while for the 6 F terms the order is F_4 , F_2 , F_3 . The unclassified term 2_3^0 has a value very close to the estimated value of the $6s8p^3P_2$ term, but the intensity relations observed for its combinations with $6s6d^3D_{2,3}$ suggest that the inner quantum number is 3 and not 2. More over if 2_3^0 were identified as $6s8p^3P_2$ a strong combination with $6s7s^3S_1$ would be expected at ν 37559. There is, indeed, a line of intensity 0 at λ 2661.74 or ν 37558.3 but it is difficult to believe this could actually be $6s7s^3S_1$ - $6s8s^3P_2$.

Table II contains the newly classified lines of Tl II and Table III shows in detail the new fine structure multiplets which have as yet been observed.

I wish to express my thanks to Dr. R. A. Sawyer through whose courtesy the essential parts of the Schüler lamp apparatus were made in the Department of Physics at the University of Michigan. My thanks are also due to

Dr. R. J. Lang for his advice in the assembling of the apparatus and in putting it into operation.

Finally I gratefully acknowledge a grant from the National Research Council of Canada which assisted very substantially in the prosecution of this work.

IONIZATION IN THE UPPER ATMOSPHERE
VARIATION WITH LONGITUDE*

BY E. O. HULBURT

NAVAL RESEARCH LABORATORY

(Received December 20, 1929)

ABSTRACT

Continuing a former paper (Phys. Rev. **34**, 1167 (1929)) the present paper gives theoretical calculations of the changes in the ionization in the upper atmosphere with longitude. The electrical conductivity of the upper atmosphere is about 1.4×10^{-5} at noon equinox at the equator and an order of magnitude less at night. The maximum density of electrons y_m varies with the latitude θ and longitude ψ , measured from noon equinox at the equator according to $y_m = 3.14 \times 10^8 \cos \theta (0.18 \sin \psi + \cos \psi)$ for the daylight hours. At night the expression is more complex. The values of y_m yield skip distances of short wireless waves roughly in accord with observation in the day but somewhat too great at night. The theory puts the shortest skip distance at 40 minutes past noon and observation in temperate zones gives 2 p.m.; the agreement is good, but not perfect.

IN A recent paper¹¹ the ionization in the upper atmosphere was worked out over the entire earth. The ionization, assumed to be caused by the ultra-violet light of the sun, was shown to explain certain facts of wireless wave propagation and of terrestrial magnetism. The variation of the ionization with latitude was described in some detail, less space being given to the variation with longitude. This paper presents the longitude calculations, and is therefore a direct continuation of the earlier paper, the nomenclature, numbering of paragraphs, equations, figures, tables and references being carried on from that paper.

33. It is assumed that the temperatures of the upper atmosphere for longitudes along the equator are given by the values of T of column 2, Table I, the degrees of latitude of column 1 being now degrees of longitude measured from high noon. For example, at 60° longitude, i.e., at 8 a.m. or 4. p.m. T is 360°K . At any point in the day hemisphere of longitude ψ and latitude θ the angular distance ζ from equatorial noon is $\cos \zeta = \cos \theta \cos \psi$ and $T = 220 + 280 \cos \zeta$. Everywhere in the night hemisphere T is 220°K . From the values of T the ionic recombination coefficient α is known at all points. The critical level z_c is nearly independent of the longitude; for example, at the equator z_c descends from the noon value of 150 km to 147 km at night, and the diurnal change at high latitudes is less.

34. In the S region the y, z curves for various longitudes were calculated for the daylight hours by the method of sections 10 and 11. The method neglected gravity diffusion of the ions and assumed that equilibrium existed between the rate of production and the rate of loss as expressed by

* Published with the permission of the Navy Department.

¹¹ Hulburt, Phys. Rev. **34**, 1167 (1929).

$$q \cos \psi - \alpha n y^2 = 0. \quad (19)$$

The curves for the equator are given in Fig. 4. ("Gravity diffusion" is a short expression for "temperature diffusion of the ions to attain gravitational

Fig. 4. Theoretical values of the density y of ion pairs in the S region of the upper atmosphere at the equator.

equilibrium.") Apart from the neglect of gravity diffusion (19) is an approximation because as the earth turns under the sun equilibrium in general does not exist. The more complete expression is

$$dy/dt = q \cos \omega t - \alpha n y^2, \quad (20)$$

where t is the time measured from high noon and ω is the angular velocity of rotation of the earth on its axis; $\omega = 7.28 \times 10^{-5}$ radians sec^{-1} . α and q are functions of the longitude ωt . Even if α and q are assumed to be constant with respect to t we are unable to solve (20) and must turn to approximate methods.

At noon at the equator $y = 5 \times 10^9$ for $z = 150$ km. At 1 p.m. y is 4.8×10^9 from (19). If there were no production of ions after 12 o'clock and the ions at 1 p.m. were those of noon decreased by recombination, y at 1 p.m. would be 1.5×10^9 , as found from (20) with $q = 0$. Since this is less than one third the value of y (19) we see that the ions at 1 p.m. are mainly those formed by the sunlight at 1 p.m. rather than those left over from noon. Therefore, the maximum value of y at $z = 150$ km is reached within less than 20 minutes after noon. Similarly, it is found that the maximum of the ionization occurs later as z becomes less until at $z = 100$ km the maximum is near 1 o'clock. Thus, except for the small shift in the maximum, (19) gives values of y which are approximately correct during the day until about 4 p.m. After 4 p.m. (19) gives values of y which are too low; for example, it would make $y = 0$ at 6 p.m., whereas at this hour many of the ions formed during the day still exist, and indeed continue to do so all night. From (19) and from (20) with $q = 0$ it comes out that at about 4.7 p.m. the number of ions in equilibrium with the

ultra-violet radiation is equal to the number left over from the earlier hours. We therefore calculate the y, z curve for 4.3 p.m. by means of (19), assume no more production of ions and calculate the y, z curves for various hours through the night from (20), with $q=0$. The night-time y, z curves for the equator are given in Fig. 4. In like manner the y, z curves throughout day and night were determined for all latitudes. The curves of Fig. 4 are probably not plotted entirely correctly, those at night being lifted up too much. Due to the cooling and contraction of the atmosphere at night and at the higher latitudes, mentioned in sections 17 and 19, the upper atmosphere is lower than at equatorial noon. The decrease in height from noon to midnight is about 25 and 15 km at 140 and 100 km, respectively. This would bring the night y, z curves closer to the noon curve than are shown in Fig. 4.

35. The height z at which a wireless wave of wave-length λ is totally reflected (refracted) at normal incidence is found by putting the refractive index μ equal to zero in the expression $\mu^2 = 1 - 2ye^2\lambda^2/\pi m$, solving for y and determining z from the y, z curve. The values of y for total reflection of waves of length 5,000, 1,000, 500, 400, 300, and 200 m are marked along the X -axis of Fig. 4. It is seen, for example, that the height reached by 1,000 m waves increases on the equator from 100 km at noon to 140 km at midnight and to 150 km in the early morning before dawn, with similar increases in the heights reached by the other long waves. The heights for total reflection at latitudes 40° , 60° , and 70° are, respectively, 5, 12, and 19 km greater than the corresponding heights at the equator. But due to the shrinkage of the atmosphere at night and at the higher latitudes the increase in the height is probably less. On the whole the heights reached by the longer waves change but little with the latitude and the time of day. This is in accord with the facts as far as they are known. It must be remembered that the observation of the height reached by wireless waves gives always an "apparent height" which is in general greater than the true height. This is due to the group velocity retardation of the wave in the ionized region of the atmosphere. Therefore, the interpretation of a height measurement is always open to some uncertainty and, in the case of the echo experiments, is often ambiguous for it is sometimes difficult to know where the echo has come from.

36. The absorption of wireless waves calculated from the y, z curves showed that in the region below the height of total reflection the intensity of 500 m waves, for example, was reduced to $1/\epsilon'$ th by passage through 20, 25 and 80 km of the medium at noon at latitudes 0° , 40° and 60° respectively. These values are, if anything, below those inferred from qualitative observation. A suitable number of electrons which undoubtedly exist in this region may be called upon to give the correct absorption. The absorption of 5,000 m waves is greater than is observed if the y, z curve is assumed to continue according to the arbitrary formula of section 10 below the height where these long waves are reflected. We may conclude, as is quite reasonable, that y becomes small and that the formula is not valid in the levels below 70 km at equatorial noon.

For 500 m waves the absorption at 4 p.m., 7 p.m. and midnight was about 0.3, 0.07 and 0.01 of the noon values. The absorption thus decreases fairly rapidly at sunset, but perhaps not quite rapidly enough. It is well known that the intensity of broad-cast waves received at some distance increases rather sharply at sunset, passing within less than two hours from its low daylight value to a high night value. Although the observations are only qualitative it would seem that they might call for a more pronounced change at sunset than the y, z ion curves can give. Electrons in the S region will disappear rapidly after sunset and may account for the sharp change in the wireless phenomena. Since 1 electron is equivalent to about 10^6 ions as far as absorption is concerned and to 10^5 ions for refraction purposes, it is possible to have the absorption in the daylight S region controlled by electrons and the refraction by ions.

Fig. 5. Theoretical values of the electrical conductivity σ of the upper atmosphere.

In this connection an interesting difficulty appears. Experiments with long waves indicate that the polarization of the received wave varies more or less rapidly with the time during the day and the night. The explanation usually given is that the upper atmosphere contains electrons which are influenced by the earth's magnetic field and cause magnetic double refraction and absorption of the wave. Ions are too heavy to give rise to appreciable double refraction except for very long waves beyond the normal wireless range. Electrons produced by the ultra-violet light of the sun, in all probability, exist in the levels below 150 km during the day, but one would expect them to disappear very rapidly at night. For example, the rate of decrease of the electron density y_e due to attachment of the electrons to oxygen molecules of density n' is $dy_e/dt = -bn'y_e$ where $b = 7 \times 10^{-14}$. At 120 km at night $n' = 1.72 \times 10^{11}$. Thus $\log_e y_e/y_0 = -0.012t$ and in 10^3 seconds or 17 minutes y_e becomes very small. The decrease is greater at the lower heights. The diffusion of electrons down from higher levels is inappreciable. Therefore, if the observations de-

mand electrons in the 70 to 140 km levels at night we shall conclude that something has been left out of the present theory. It is possible that the interference of a number of rays may give rise to changes in the polarization of the received wave quite apart from magnetic double refraction effects.

37. From the y, z curves the values of the electrical conductivity σ of the S region were calculated by means of (12) and were plotted in Fig. 5 for various longitudes and latitudes. In Fig. 5' the night values of σ are given on a larger scale. Summing up the values of σ over the light and dark hemispheres gives the ratio of the total night to day conductivity to be $1/20$; this value was used in section 18. The electrical conductivity of copper is 5.9×10^{-4} and of mercury is 1.06×10^{-5} c.g.s.e.m. u. The conductivity of a 1 cm^2 column vertically upward through the S region of the atmosphere is about 1.4×10^{-5} at equatorial noon and 10^{-6} at sunset, and is therefore equivalent in these two cases to that of 14 and 1 mm of mercury, respectively.

38. Concerning the variation of the D ions with longitude there is little to add to what has already been said in sections 13 to 16. The calculations of the D ions were on the whole pretty rough because so many simplifying assumptions were made. To improve the calculations appears to be intricate and the mathematical difficulties promise to be appreciable. At equatorial noon the magnetic susceptibility of each cm^3 of the D region is about two orders of magnitude greater than that of bismuth, bismuth being the most strongly diamagnetic substance known.

39. The electrons were shown¹ to attain their maximum density y_m at a height of 190 km at summer noon. The y_e, z curve for noon at $\theta = 17^\circ$ (as at Washington, D. C., on June 22) is given in curve 1, Fig. 2, reference 1, in which $y_m = 3 \times 10^5$. We use this curve and adopt the simplifying assumption (reference 1, page 1029) that during changes in the curve, which occur during the day and night, the electron density y_e at each point on the curve changes in the same proportion. This enables all the calculations of the y_e, z curve to be reduced to a calculation of the changes in y_m . The physical justification for this assumption lay in the fact that most of the electrons were produced somewhere above the maximum and diffused rapidly downward to build up their maximum density approximately at a height where the loss due to attachment to oxygen molecules became greater than the supply due to diffusion from above, the loss increasing and the rate of diffusion decreasing as z became less. Therefore, if the rate of production q grew less y_e diminished at all points of the curve, and the assumption is that y_e diminishes equally at all points of the curve. Using the calculations of reference 1, page 1030, and changing them to refer to the somewhat higher day temperatures of the present paper, the total loss sec^{-1} of electrons above y_m due to attachment is 1.59×10^8 or $530 y_m$. The loss due to the recombination of electrons with positive ions is negligible; this is fortunate, for the recombination term involves a y_m^2 which would make the equation hard to solve. The loss due to the electrical drift downward during the day with velocity v is $250 y_m$, using an average value $v = 250 \text{ cm sec}^{-1}$ among the values of v of column 9, Table I. The loss due to gravity diffusion across the maximum is $166 y_m$, but this we leave

out. For gravity diffusion can not occur in its full extent simultaneously with the electrical drift as it involves molecular collisions which interfere with the drift. Therefore the rate of loss is approximately $(530 + 250) y_m = 780 y_m$.

The total number of electrons above the maximum is $5.76 \times 10^{11} = 1.95 y_m$. The rate of production is $q \cos \theta \cos \omega t$ where q is the rate at equatorial noon equinox, i.e., the sun directly overhead. Then

$$dy_m/dt = q \cos \theta \cos \omega t - 780 y_m / 1.95 \times 10^6. \quad (21)$$

Solving

$$y_m = \frac{q \cos \theta}{16 \times 10^{-8} + \omega^2} (\omega \sin \omega t + 4 \times 10^{-4} \cos \omega t). \quad (22)$$

Putting $t=0$, $y_m = 3 \times 10^5$, $\theta = 17^\circ$ and $\omega = 7.28 \times 10^{-5}$ in (22) gives $q = 130$, and (22) becomes

$$y_m = 3.14 \times 10^5 \cos \theta (0.18 \sin \omega t + \cos \omega t). \quad (23)$$

With this expression the values of y_m were calculated over the daylight hemisphere and are plotted in the full line curves of Fig. 6. The maximum value of y_m occurs at about 40 minutes past noon. Formula (23) is not valid at night for the sunset to sunrise voltage E reverses in sign at sunset and hence the downward daytime electrical drift velocity v changes after sunset to an up-

Fig. 6. Theoretical values of the maximum electron density y_m in the upper atmosphere.

ward velocity. At night (18) is used. (23) gives too low values of y_m as sunset is neared, for at this time the rate of loss of the electrons grows less because the downward electrical drift diminishes due to the decreasing E and the attachment coefficient diminishes due to the cooling temperature. Therefore the night curves, calculated from (18) and plotted in the dotted lines of Fig. 6 were joined to the day curves at 5 p.m.

40. The skip distance $2s$ for a wireless wave of length λ is given approximately by

$$2s = 2h(\pi m / y_m e^2 \lambda^2 - 1)^{1/2}, \quad (24)$$

where e and m are the electronic mass and charge, respectively, and h is the value of z for y_m . h was taken to be 190 km with the sun directly overhead, to be 140 km along the sunset and sunrise longitudes and to vary between these limits over the day hemisphere according to $\cos \theta \cos \omega t$. During the night the electrons move upward with a velocity roughly 250 cm sec^{-1} or 9 km hr^{-1} . Therefore h increases 9 km each hour during the night being 140 km at night-

fall and 210 km 8 hours later. With these values of h and with y_m from the curves of Fig. 6, the values of $2s$ for $\lambda 32$ meters were calculated from (24) and are plotted in Fig. 7. The skip distances for other short wireless waves calculated from (24) are approximately proportional to those for $\lambda 32$ meters. During the day the skip distance of Fig. 7 agree within 50 percent with the observed values as far as they are known; in the small hours of the night the calculated values appear to be on the whole 1.5 to 2 times too great.

Equation (24) is not exact for it leaves out of account the magnetic field and the curvature of the earth; the neglect of the first gives too long and of the second too short skip distances, the error due to the approximations being in general less than 30 percent. (24) also assumes sharp reflection of the wave at a height h and therefore neglects refraction by ions and electrons below y_m . The inclusion of this refraction will lessen the calculated skip distances. The

Fig. 7. Calculated values of the skip distance $2s$ for a 32 meter wireless wave.

skip distances of Fig. 7 are a minimum at 40 minutes past noon, the time when y_m is a maximum. Observation in temperate latitudes puts the shortest skip distance at about 2 o'clock. The agreement between theory and experiment is therefore good but not perfect. It is difficult to give a satisfactory explanation of the slight discrepancy; perhaps the value of the attachment coefficient is a little high, or perhaps there are shifts in the distribution of the ionization below the maximum which cause a warping of the ray paths.

41. In conclusion, it may be stated that an ionization produced by the ultra-violet light of the sun has been worked out which accounts in a general way for wireless wave propagation phenomena over the earth and for the part of the earth's magnetic field of external origin and its diurnal variations. We can not regard, however, the ionization which has been obtained as a unique solution of the problem of the ionization of the upper atmosphere. The ionization can be modified within limits in a number of ways without disturbing

the present conclusions, and probably some modification may be desirable for the numbers of ions and electrons which have been used may be slightly too great.

With the sun directly overhead D is 1.5×10^{16} atomic nitrogen ion pairs from 150 to 180 km, or the ion density is 10^{10} . From the relation¹²

$$\mu^2 = 1 - ye^2\lambda^2 / (1 - He\lambda / 2\pi cm)\pi m, \quad (25)$$

it is seen that 10^{10} atomic nitrogen ions give the same refraction for 40 meter waves as 3.2×10^5 electrons. Therefore at equatorial noon either the ions or the electrons will account for the wireless skip distances equally well, but both the 3.2×10^5 electrons and the 10^{10} ions are unnecessary, although to be sure there is no objection to having both if they are at different levels. Early in the morning and late in the afternoon the refraction of the ions falls below that of the electrons, as calculated from the values of y and y_e of the foregoing paragraphs, and at night it rises above the electronic refraction. If the observational facts of short wireless waves call for a refraction predominately electronic there are several ways in which the refractive effects of the ions may be decreased without disturbing the present development. One may keep the same number of ions and suppose that, say, one-half are molecular ions. This will decrease their refraction, change the drift currents and modify the calculations throughout, but will not change any of the values by as much as 100 percent. Or, one may decrease the number of ions and assume higher noon temperatures. In illustration, let us suppose that the number of ions were $1/2$ and the noon temperatures 2 times the respective values which have been used. This will multiply the day values of σ and E by $1/4$ and $3/2$, respectively. The currents in the D and S regions for day and night, instead of being, respectively, about 11.6, 8.7, 2.3 and 0.6, become 6, 3, 2.5 and 0.5 millions of amperes. The steady current around the earth and the diamagnetism are unchanged.

On the other hand one can not be entirely certain that it is the ions which should be reduced. Actually the ions will give very closely the same skip distance-wave-length relation as the electrons. Therefore if the refraction of short wireless waves were due to ions rather than to electrons the skip distance theory¹² would be unchanged. In this case it would be an "ion limitation" theory rather than an "electron limitation" theory. A sufficient number of electrons could be assumed such that by their magnetic double refraction and absorption they would account for the dip in the wireless range curve at $\lambda 200$ meters¹³ and the polarization phenomena. It is doubtful whether at the present time the observational data permit a final decision among the various possibilities. We may express the view, based on the complexity of wireless wave behavior, that some complex modification may be the one which will best account for all of the facts. That is, that perhaps the ions and electrons are present in such numbers that their refractions are about equal, and that during certain hours of the day or night and at certain latitudes the refraction of wireless waves is controlled by electrons and at other times and latitudes by ions.

THE SURFACE HEAT OF CHARGING

BY KARL F. HERZFELD

PHYSICAL LABORATORY, JOHNS HOPKINS UNIVERSITY

(Received December 24, 1929)

ABSTRACT

In recent papers by Bridgman, Langmuir and Tonks, and the author, the deviation of the constant A of *thermionic emission* from the theoretical value has been linked with the surface heat of charging and the *temperature variation of the photoelectric threshold*. In the present paper, at least a part of this effect is explained by the heat expansion of the material together with the dependency of the *work function* on the volume. Numerical calculations both for the deviations of A and for the temperature change of the threshold are made and compared with experiments. Before deciding whether the explanation given here is complete it will be necessary to calculate the space-charge effect of the electrons in the transition layer on the surface of the metal.

I. INTRODUCTION

THERE is considerable interest shown in the discussion of the formula for the thermionic emission, to which Richardson gave the form

$$i = BT^2 e^{-b/T}. \quad (1)$$

Equivalent to this, but better suited for our purpose, is the formula for the equilibrium density of the electron gas.

$$c = AT^{3/2} e^{-q/kT}. \quad (2)$$

in which A should be a universal constant^{1,2}

$$A = (2\pi mk)^{3/2} / Nh^3. \quad (3)$$

Here the exponent $3/2$ of T comes about by putting the specific heat of the electron gas equal to $3R/2$, the specific heat of the electrons in the metal zero.³

Independent of this assumption, one can give general formulas connecting vapor pressure and heat of evaporation.^{4,5,6} For example Lane² and Schottky⁷ write in generalization of (2)

$$c = AT^{3/2}e^{-\mu_s/kT} \quad (4)$$

where μ_s is the chemical potential of the electrons in the metal instead of their potential energy (in other words, the assumptions leading to (2) are equivalent to say $\mu_s = q$) and then proceeds to allow for μ for example a linear variation with T . This procedure is thermodynamically quite correct but leaves the question why μ is a linear function of T unanswered.

As a next step, one can introduce the specific surface heat of charging as the specific heat which enters into the thermodynamical equations.^{6,8,9} It has been shown that such an effect might change the apparent value of A , the value of which agrees well experimentally with (3) in many cases but by no means always.

One can on the other hand consider the fact that the mutual potential energy which holds the electrons in the lattice will depend on the lattice distance and if heat expansion occurs will accordingly depend on the temperature.¹⁰ This is closely connected with the temperature variation of the long-wave-length limit of the photoelectric effect. How to treat such a case has been discussed in a short paper¹¹ but no formulas have been given and some remarks there seem now incorrect.

Bridgman,¹² in a paper that appeared before the one last mentioned has shown quite clearly how the two effects of a variation of the photo-electric stopping potential with temperature and the surface heat of charging are connected and will modify A .

The present paper, while using a different scheme of thermodynamical calculations than Bridgman because it seems simpler, is intended to supplement it by showing just what values the surface heat of charging must have.

We propose first to give the calculations for a somewhat simplified case, in the second part we will discuss a few subtle points to justify our method of procedure.

II. CALCULATIONS FOR A SIMPLIFIED CASE

1. The free energy.

Consider a piece of metal, insulated and surrounded by vacuum. Call the number of electrons the metal contains in excess of the neutral state n , the free electrons in the vacuum n' . Let p be the pressure, V the volume of the metal, V_0 its normal volume when neutral and at zero pressure, $\Delta = (V - V_0)/V_0$.

We then write the formula for the free energy F of the whole system.

$$F = U(V) - nq(V) - \frac{1}{2}en\phi - T\Phi\left(\frac{h\nu}{kT}\right) - Tn\tilde{\Phi} + n'(\mu_G - kT).$$

⁸ L. Tonks and I. Langmuir, *Phys. Rev.* **29**, 524 (1926); L. Tonks, *Phys. Rev.* **32**, 284 (1928).

⁹ P. W. Bridgman, *Phys. Rev.* **27**, 143 (1926).

¹⁰ O. W. Richardson, *Phil. Mag.* **23**, 594 (1912).

¹¹ K. F. Herzfeld, *Sommerfeld Festschrift*, Leipzig, 1928, p. 143.

¹² P. W. Bridgman, *Phys. Rev.* **31**, 90 (1928).

Here $U(V)$ is simply the (elastic) energy of the neutral metal. On account of deviations from neutrality, there is additional energy, an unelectric part¹³ $-nq(V)$ and an electric part $(-1/2)en\phi$. In contradiction to Schottky¹³ but in accord with Eckardt¹⁴ we call electric only the part of the field due to excess charges and having accordingly a long range. This part can be changed by connecting the plate with outside sources. Accordingly $\phi = 0$ means that there is no field of long range present. The energy then necessary to remove an electron is called the unelectric part $\tilde{q}(V)$. Φ is the integral

$$\Phi\left(\frac{h\nu}{kT}\right) = \int_0^T \frac{dT}{T^2} \int_0^T C_v dT \quad (5)$$

for the specific heat of the metal and will be usually a Debye function. Through ν , it will depend on the volume. We assume, (for the discussion of this assumption see under III) that ν does not depend explicitly on the charge.

$n\tilde{\Phi}$ would be the corresponding integral taken over the specific heat of the electrons in the usual sense, as calculated by Sommerfeld.³ $\partial(n\tilde{\Phi})/\partial n$ corresponds to the part variable with temperature in Sommerfeld's expression of $2kT \ln A$ (which has as physical meaning just the electron part of our $\partial F/\partial n$) and is negligible up to 3000° ($2 \cdot 10^{-3}$ compared with 1, although it accounts for Thomson- and thermoelectric effects).

Finally, μ_G is the usual expression for the chemical potential of the electron gas

$$\mu_G = kT \ln c + (3/2)kT \ln T + kT \ln A. \quad (6)$$

2. Equilibrium formula.

In equilibrium, F will be a minimum in respect to the possible variations, namely of n (electron emission) and of volume. The first condition will give the equilibrium concentration, the second the equation of state of the charged metal (in making this latter variation, we neglect the fact that an increase of the volume of the metal will decrease the volume of the electron gas).

$$0 = -\left(\frac{\partial F}{\partial n}\right)_v = q(V) + \frac{1}{2}e\phi + \frac{1}{2}en\frac{\partial \phi}{\partial n} + T\frac{\partial}{\partial n}(n\tilde{\Phi}) + \mu_G \quad (7)$$

$$0 = -p = \left(\frac{\partial F}{\partial V}\right)_n = \frac{\partial U}{\partial V} - n\frac{\partial q}{\partial V} - \frac{1}{2}en\frac{\partial \phi}{\partial V} - \frac{h}{k}\Phi\frac{\partial \nu}{\partial V} - Tn\frac{\partial \tilde{\Phi}}{\partial V}. \quad (8)$$

As at least in first approximation $n\partial\phi/\partial n = \phi$ and as we have decided to neglect $\tilde{\Phi}$, we get from (7)

$$-\mu_G = q(V) + e\phi \quad (9)$$

¹³ W. Schottky, Handb. d. Exp. Phys. Vol. XIII, 2 half p. 14 Leipzig 1928.

¹⁴ C. Eckardt, Zeits. f. Physik 47, 38 (1928).

¹⁵ In this we include the part of the internal electron pressure effect which does not depend on temperature, namely $-W_i$ (Sommerfeld) so that $q = W_a - W_i$.

or

$$c = AT^{3/2} e^{-(q(V) + e\phi)/kT} \quad (10)$$

which for constant volume of the metal, is identical with the usual form (2).

The problem is then to find $q(V)$. Here we use the following approximations: As U refers to the neutral metal, we introduce the common compressibility κ and write, using a familiar development in powers of Δ

$$U(V) = U_0 + V_0 \Delta^2 / 2\kappa. \quad (11)$$

Furthermore, we assume

$$q(V) = q_1 - q_2 \Delta \quad (12)$$

with the expression

$$q_2 = -V_0 \partial q / \partial V.$$

This gives

$$\frac{\Delta}{\kappa} + \frac{nq_2}{V_0} - \frac{1}{2} en \frac{\partial \phi}{\partial V} + \frac{h\nu}{kV_0} \Phi' \gamma = 0 \quad (13)$$

using Gruneisen's result,^{15a} that

$$-\gamma = (V_0/\nu) \partial \nu / \partial V \quad (14)$$

is a constant, namely about 1-3 for many metals.

Using the expansion coefficient α for the uncharged metal ($n=0$), which is according to Gruneisen given by

$$\int_0^T \alpha dT = -\kappa \frac{h\nu}{kV_0} \gamma \Phi' \quad (15)$$

we find

$$\Delta = \int_0^T \alpha dT - nq_2 \frac{\kappa}{V_0} + \frac{1}{2} en \kappa \frac{\partial \phi}{\partial V}. \quad (16)$$

For the approximately neutral metal, $n=0$, $\phi=0$, we have

$$c = AT^{3/2} e^{-q_1/kT} \exp \left[\frac{-q_2}{kT} \int_0^T \alpha dT \right]. \quad (17)$$

The last factor is the deviation from the formula (2). It is simply the change in q due to the total expansion of the metal up to T .

Equation (17) can be written for sufficiently high temperature

$$c = A' T^{3/2} e^{-q_1/kT} \quad (18)$$

$$A' = A \exp \left[\frac{q_2}{kT} \int_0^T \alpha dT \right] = A e^{q_2 \alpha / k} \quad (19)$$

^{15a} E. Gruneisen, Ann. d. Physik 39, 257 (1912).

3. Calculation of q_2 and numerical value of A' .

It is possible to get an estimate of q_2 . We have first to remember that q is a difference between the potential energy of an electron in the metal (Sommerfeld's W_a) and the effect of the internal pressure. (W_i according to Sommerfeld.) Therefore

$$-q_2 = V_0 \frac{\partial W_a}{\partial V} - V_0 \frac{\partial W_i}{\partial V}$$

Bethe¹⁶ attempts a theoretical calculation of W_a ; it is composed of a contribution from the positive ions, which is, for a given size of the ions, proportional to their number per unit volume and which we call therefore

$$W_a^+ + V_0/V$$

and a contribution from the electrons, inversely proportional to the distance, or

$$W_a^-(V_0/V)^{1/3}.$$

Finally, W_i is proportional to the $2/3$ power of the number of electrons per cm^3 .

If we assume that compression does not change the total amount of electrons per atom, we have (W_a^+ , W_a^- , W_i^0 constants)

$$q = W_a^+ \frac{V_0}{V} + W_a^- \left(\frac{V_0}{V} \right)^{1/3} - W_i^0 \left(\frac{V_0}{V} \right)^{2/3}. \quad (20)$$

Then

$$q_2 = W_a^+ + \frac{1}{3} W_a^- - \frac{2}{3} W_i^0. \quad (21)$$

According to Bethe's calculations for nickel, W_a^+ is about 13 volts, W_a^- 6 volts, W_i^0 15 volts, which would make $q_2 \sim 5$ volts.

If we write $\alpha = \alpha' \times 10^{-5}$, $q_2 = +q_2'$ volt, we have

$$e^{q_2 \alpha / k} = 10^{0.059 q_2' \alpha'} \quad (22)$$

From this it follows: A is always apparently increased $A' > A$. For $q_2' \alpha' < 10$ the factor multiplying the theoretical A is not larger than 3, which is within the limits of the experiment. If the above estimate of q_2 is correct, this means for metals with low expansion coefficient ($\alpha' < 2$), that the theoretical value of A can be made to fit the results.

But we have to expect much higher A 's if α' is larger. $\alpha' = 9$ (linear expansion coefficient 3), $q_2' = 5$ means already $A' = A \cdot 10^{2.25} \sim 180A$; $\alpha' = 15$, $q_2' = 6$ means $A' = 30.000A$.

While this is in the right order of magnitude,^{18,19} we can give no reason why a large A' should always go with a high q_1 .

¹⁶ H. Bethe, Ann. d. Physik **87**, 55 (1928).

¹⁷ The factor $\exp[-(1/k) \partial(n\Phi)/\partial n]$ which is responsible for the thermoelectric effects has been neglected.

4. Temperature change of the heat of evaporation.

We are first going to calculate the heat of evaporation of the electron and show that the deviation can be interpreted as a contribution of the specific surface heat of charging, not to C_v , but to $C_p - C_v$.

The heat of evaporation of an electron at constant volume of the metal would be

$$q(V) + 3RT/2 + e\phi \quad (23)$$

the middle part coming from the specific heat of the electron gas. The contribution of the specific heat of the electrons in the metal has been neglected.

At constant pressure, we have to add to (23)

$$T^2 \left(\frac{\partial}{\partial V} \frac{\mu}{T} \right)_{T,n} \left(\frac{\partial V}{\partial T} \right)_{p,n}$$

or take simpler

$$T^2 \left(\frac{\partial}{\partial T} \frac{\mu(p, T)}{T} \right)_{p,n} + \frac{3}{2} RT. \quad (24)$$

This is, with

$$\mu(p=0, T) = -q_1 - \frac{h\nu}{k} q_2 \frac{\gamma}{V} \kappa \Phi' \quad (25)$$

from (7) for the uncharged plate, $n=0$, leads after a short calculation to the following formula in which the value of Φ has been introduced

$$q_1 - q_2 \frac{\gamma}{V_0} \kappa \left(C_v T - \int_0^T C_v dT \right) + \frac{3}{2} RT. \quad (26)$$

Instead of the last $3RT/2$, $2RT$ or $5RT/2$ might have to be introduced, depending on which heat is actually measured.⁶

The interesting point is that for moderate temperatures, $C_v T - \int_0^T C_v dT$ is a constant or, in the presence of zeropoint energy in the vibrations of the solid, even zero. The exponent $-q_1/RT$ in (3) gives therefore at moderate temperatures the real heat of evaporation (apart from the member $3RT/2$, which is due to the electron gas).

In making this statement, we have again neglected the increase with temperature of the kinetic energy of the electrons in the metal as too small to detect. We can expect to find a change of the heat of evaporation with temperature:

(a) at high temperature, where C_v increases

$$C_v = C^0 + C' T$$

$$C_v T - \int_0^T C_v dT = \frac{C'}{2} T^2, \quad \Delta q = -q_2 \frac{\gamma}{V_0} \kappa \frac{C'}{2} T^2.$$

This increase will not modify greatly the last factor in (17) because it occurs at high temperatures ($1/T$).

(b) at low temperatures, where quantum effects appear in the specific heat, there will be an increase in the heat of evaporation (apart from $3RT/2$) with decreasing temperature up to the amount

$$q_2 \gamma \kappa N h \nu / V_0.$$

The value of the specific surface heat of charging at constant pressure follows from (26) to be

$$q_2 \frac{\gamma k}{V_0} T \frac{\partial C_v}{\partial T}$$

(C_v specific heat of the metal at constant volume.) Bridgman^{9,12} has shown that if (2) is valid and A' different from A , the specific surface heat of charging must be 0 and there must exist an entropy difference between the charged and the uncharged surface at zero temperature contrary to Nernst's heat theorem. In the case considered here the specific surface heat of charging is zero at zero temperature, takes then positive values and decreases to zero again for high temperatures. Accordingly (2) is valid at very low temperatures with the theoretical A , ceases to be valid afterwards and becomes valid again at high temperatures with $A' > A$. This hump of the specific heat at low temperatures is then responsible for the deviation of A' from A . If one would extrapolate formula (2) with A' different from the theoretical value to zero temperature one would find an entropy difference. A very similar situation is present in a number of chemical reactions. The whole situation is bound up with the fact that the expansion coefficient disappears at zero temperature which fact itself is again connected with Nernst's theorem.

Numerical calculations for the case of potassium give the following result: We use

$$\gamma = 1.34^{20} \quad \kappa^{21} = 35.6 \times 10^{-12} \quad V_0 = 45 \quad h\nu/k = 99^{22}$$

and for $C_v - (1/T) \int_0^T C_v dT$ tables given by Simon.²³

If we take $q_2 = 5$ volt we find

T	$\beta\nu/T$	$CT - \int C dT$ (cal/Mol)	Δq (millivolts)
495	0.2	0	0
198	0.5	8	1.7

5. Photoelectric threshold.

Offhand, one could be doubtful whether the photoelectric threshold is determined by the energy or the free energy of the electrons in the metal. But Bridgman has proved the connections between threshold and contact potentials, and there is no doubt that the contact potentials are determined by the free energy or, more exactly, the chemical potential μ .

The temperature variation of the threshold is then given by

$$q_1 + q_2 \frac{\gamma}{V_0} \kappa \frac{h\nu}{k} \Phi' = q_1 - q_2 \frac{\gamma}{V_0} \kappa \int_0^T C_v dT = q_1 - q_2 \int_0^T \alpha dT.$$

That means, that for an increase of 100°C and $q_2 \sim 5$ volts, the change in the photoelectric threshold is as follows.

K	Al	Mg	Zn	Cu	Ag	Au	Fe	Ni	Pt	Pb	Sb	
125	36	39	43	25	29	21	17	23	15	43	18	millivolts.

Comparing this with experiments, it seems reasonable that such a change could not be detected in the work of Millikan and Winchester²⁴ who heated Al, Mg, Zn, Cu, Ag, Au, Fe, Ni, Pb, Sb 100° and of Varley and Unwin²⁵ who varied the temperature of Pt 300°, corresponding to changes of less than 50 millivolts. It is more astonishing that Millikan and Winchester²⁴ found no change for Al between 50 and 350° (110mv) and Ladenburg²⁶ for Au, Pt, Ir up to 860° (150mv) and that Dember²⁷ could not detect any effect on K on heating it to 67°, but it is difficult to estimate how much a change in the long-wave-length limit would affect the current measured by these investigators.

Recently Du Bridge²⁸ detected a change in current upon heating platinum to 1200° and narrowed down the wave-length shift to a region between 1943-1973Å; 30Å would correspond to 90 while $q_2 \sim 5$ V would lead to 180mv. Measurements of Suhrmann²⁹ give a few percent shift in Ag, Au, Pt between room temperature and liquid air. Finally Ives³⁰ has found a shift for K in the same interval of 220mv while $q_2 = 5$ would give 250 (actually it should be less on account of the smaller coefficient of expansion at low temperatures). It seems therefore that the present theory gives the right order of magnitude.

It should be mentioned in conjunction with the fact that the oxide-coated cathodes have a particularly high A' , that Koppius³¹ found a very strong variation of their threshold with the temperature.

III. JUSTIFICATION OF METHOD OF PROCEDURE

1. We have made our calculations as if the evaporating electron were taken from the interior and have not said anything in particular about the surface. Here we have to distinguish two steps in the equilibrium condition (7) we have put the expression for the thermodynamical potential of an electron deep in the interior of the vessel equal to one in the gas. But as Schottky pointed out, this is justified as the numerical value of μ (not the form of μ) must be the same for an electron in the interior as it is in the surface on account of the internal equilibrium of the electrons. On the other hand, the particular expression for the potential energy (q) in the interior, as calculated by Bethe, might be wrong; this value might be influenced by the surface. But it seems reasonable that this would not change the order of magnitude of q_2 , and our calculation does not claim more.

2. We did not include, "electrical contributions," as we defined the Volta potential ϕ as being due to the total charge and we assume this to be zero (compensation for Volta potential in the actual thermionic experiment). The difference between this case and the usual case, for example in the thermodynamics of gases where differentiation at constant pressure (analogous to ϕ) and constant volume (analogous to en) makes a difference even for $n=0$, comes from the fact that

$$pV = nkT$$

and therefore $\partial(pV)/\partial n = kT$ even for $n=0$ while here $ne\phi$ is proportional to n^2 and therefore $[\partial(ne\phi)/\partial n]_{n=0} = 0$.

The reason we have deviated from Schottky's¹³ definition, which amounts here to saying that the non-electric part in the differences of the (total and free) energy is the one remaining, if the two places to be compared were brought to the same potential, is the following: With this definition all differences in potential energy of the electron would belong to the electrical part. Indeed, the electrical potential of a place is defined only by the work necessary to bring a test charge (electron) there. Accordingly the difference in potential energy q inside and outside of the metal would belong entirely to the electrical part, which does not seem advisable. On the other hand, it is always possible, by measuring at a sufficient distance, to state whether a (large) body is charged. We define as the non-electric part of the (free or total) energy of an electron in respect to a (large) body the part which would be alone present if the body as a whole were uncharged.

In passing, it may be said that this together with the emphasis that in measuring thermionic currents one has always to correct for the Volta potential, that is one always takes care to have $\phi=0$, gives a clear view of the situation in the presence of surface layers.

3. We have assumed that Φ or the specific heat C_v of the metal at constant volume depends upon n only indirectly through the volume. If we now drop this assumption, (8) and (13) remain unchanged, but in (7) we must add

$$-T \left(\frac{\partial}{\partial n} \Phi \right)_{v,T} = -\frac{h}{k} \Phi' \frac{\partial \nu}{\partial n}$$

which then produces finally on the right hand side of (17) another factor

$$\exp \left[\frac{h}{k^2 T} \Phi' \frac{\partial \nu}{\partial n} \right].$$

Now we can write, for a plate containing N atoms, at sufficiently high temperature

$$\frac{h}{k^2 T} \Phi' \frac{\partial \nu}{\partial n} = -\frac{h}{k^2 T} 3Nk \frac{kT}{h\nu} \frac{\partial \nu}{\partial n} = -3N \frac{\partial \ln \nu}{\partial n}$$

or better

$$-\partial(\Sigma \ln \nu) / \partial n$$

where the sum is to be extended over all the vibrations which make up the heat movement of the plate. Therefore³²

$$\exp \left[\frac{1}{R} \left(\frac{\partial \Phi}{\partial n} \right)_{v,T} \right] = \prod_i \exp \left[- \left(\frac{\partial \ln \nu_i}{\partial n} \right)_v \right].$$

If we would assume that the removal of an electron affected only three vibrations (in a primitive picture the vibrations of one atom), we could say safely that the new frequency would lie between half and the double of the original frequency, or

$$\left| \frac{\partial \ln \nu_i}{\partial n} \right| < 1 \quad i=1,2,3 \quad \frac{\partial \ln \nu_i}{\partial n} = 0 \quad i>3.$$

Then, the additional factor in (19) would lie between e^{-3} and e^3 1/20 and 20. If, as will be the case, the change affects all vibrations, it still seems reasonable that

$$\left| \sum \frac{\partial \ln \nu}{\partial n} \right|$$

will be not much larger than 3 and therefore, a direct influence of a removal of electrons on the specific heats at low temperature will probably not influence A' as strongly as the indirect effect through the volume.

4. The most important assumption however that we have made is the omission of a part of q which would be explicitly dependent on temperature. Now the part in the potential energy of an electron which is due to the surrounding charges, as calculated by Bethe,¹⁶ is not dependent directly on temperature (the heat movements of the positive ions will upon averaging have no effect of the first order). But there might be another contribution³² due to

³² W. Schottky, reference 13, p. 96f. See also E. D. Eastman, Jour. Am. Chem. Soc. **48**, 552 (1926), C. Zwicker, Physica, **9**, 321 (1929).

an electric double layer or space charge, which might be formed on the surface of the metal where the electron density drops gradually off. This might depend on T , not in the part farther in, where the electron density is still high, the electron gas degenerate and therefore its μ independent of T , but in the outside layers. How much these contribute, can not be estimated until a calculation has been made.

The only thing to be said is that the part discussed previously gives the right order of magnitude.

IV. OTHER APPLICATIONS

The method which we have developed here can be applied similarly to an ordinary solution, in which the mutual potential energy between the solvent and the dissolved molecules depends on the distance between them and accordingly varies indirectly with the temperature on account of the heat expansion of the solvent.

CHANGE OF SPACING OF POSITIVE COLUMN STRIATIONS WITH TEMPERATURE

By F. M. SPARKS AND CHARLES T. KNIPP
UNIVERSITY OF ILLINOIS

(Received December 19, 1929)

ABSTRACT

Cassen's prediction (Phil Mag. 268, 948, Nov. 1926) that the separation of the striations in a discharge tube should increase almost linearly with the absolute temperature is verified for the wide blue striations. For the narrow striations, the separation first decreases, but in general reaches a minimum, after which the separation increases as predicted.

FROM theoretical considerations, Cassen¹ predicts that the distance between striations in the positive column of a discharge tube should increase almost linearly with the absolute temperature, and that the addition of an impurity may greatly change the spacing.

A vertical discharge tube was heated in a liquid bath contained in a large vertical glass tube. An electric heating coil was placed in the bottom of the bath and the temperature controlled by an external resistance. Two thermometers were placed in the bath at different heights to obtain the temperature. A large flask was connected to the discharge tube to minimize the change in pressure due to change in temperature of the tube. To secure steady striations which could be measured with a cathetometer, a potential of 3000 volts from small storage cells was used. The current was controlled by a water resistance and measured with a milliammeter.

Fig. 1. Wide striations at a pressure of 1 mm Hg.

Fig. 2. Wide striations at a pressure of 1 mm Hg.

Hydrogen was used in the discharge tube because it gives striations over a much greater range of conditions than the other ordinary gases. Only the blue striations were obtained, these being due to impure hydrogen.² The pressures used were such that both the wide and the narrow blue striations appeared.³ To detect any temperature lag or change in character of the gas, the separations were noted with both increasing and decreasing temperature.

The separation was gotten by measuring across several striations and

¹ B. M. Cassen, Phil Mag. 268, 948 (1926).

² Handbuch der Physik, vol. 14, p. 298.

³ Handbuch der Physik, vol. 14, p. 300.

dividing this distance by the number of striations measured. The separation in millimeters was plotted against the temperature of the bath in degrees Centigrade. Measurements were made for different values of the current because the separation varies with current.⁴

Figure 1 shows three curves, obtained at the same time, for current values of 0.75, 1.5, and 3 milliamp. Measurements were begun at room temperature, the unbroken line indicating readings with increasing temperature, and the broken line being for decreasing temperature. Figure 2 shows another set of curves, for currents of 1.5, 2.25, 3, and 3.75 milliamp. Both these sets of curves are for the wide striations, at pressures of about 1 mm Hg. Figures 3 and 4 represent data for the narrow striations, at pressures of 2.5 and 1.7 mm.

Fig. 3. Narrow striations at a pressure of 2.5 mm Hg.

Fig. 4. Narrow striations at a pressure of 1.7 mm Hg.

In Fig. 3 the readings were begun at 155°C, the temperature lowered to 55°, then increased to 165°, and the last readings at room temperature were made the next day. In Fig. 4 no reading was made for a current of 6 milliamp. at 150° because the cathode became too hot. Figures 1 and 3 were made with prepared hydrogen, using one discharge tube, and Figs. 2 and 4 with commercial hydrogen, using a different tube.

Figures 1 and 2, representing the wide striations, agree with Cassen's prediction that the separation should increase almost linearly with the temperature. Figures 3 and 4, representing the narrow striations, show that the separations may first decrease but that they reach a minimum value and then increase linearly with the temperature. The curves for current values of 4.5, 5.25 and 6 milliamp. in Fig. 4 show only an increase in separation, which is in exact accord with the prediction. However, the minimum value of the separation seems to be shifted toward lower temperatures as the current is increased so that these curves might be expected to be similar to the others in the same figure, but with a minimum at some temperature below room temperature. Figure 3 also shows the shifting of the minimum to the left with increasing current. The deviation from Cassen's predictions might be explained by saying that his simplifying assumptions are valid only under certain conditions.

A series of curves was also plotted for hydrogen at 2.5 mm, after successive additions of impurity. The general shape of the curves was similar to those of Fig. 3, but they were shifted down to smaller values of separation, reaching a minimum, and then were shifted up to greater values.

PERSISTENCE OF VELOCITY AND THE THEORY
OF SECOND ORDER GAS REACTIONS

BY LOUIS S. KASSEL*

GATES CHEMICAL LABORATORY, CALIFORNIA INSTITUTE

(Received December 10, 1929)

ABSTRACT

R. H. Fowler has stated that if, in second order gas reactions, it is supposed that reaction occurs whenever two reactant molecules collide with sufficient velocity, then the deviation from the Maxwell distribution law which would result is so great that this law cannot be used in calculating the rate of the reaction. It is shown that this view is sometimes in error, and that in a mixture of molecules of nearly equal mass reacting in this way the molecular velocities do not diverge appreciably from the predictions of the Maxwell law.

IT IS an experimental fact that the rates of all the known second order gas reactions can be represented, at least within a factor of 5 or 10, by the simple expression $Ze^{-E/RT}$, where Z is the number of collisions between reactant molecules, calculated in accordance with the methods of kinetic theory, and E , the energy of activation, is an experimental constant for each reaction. There are a number of simple theories which are able to predict an equation of this form. In particular, if it is assumed that reaction occurs at every collision for which the relative velocity parallel to the line of centers at the instant of collision is at least V_0 , it is found¹ that the rate is $Ze^{-E_0/RT}$, where $E_0 = MV_0^2/2$ and M is the reduced molecular weight $M_1M_2/(M_1+M_2)$. If it is supposed that the reaction occurs whenever the relative velocity of the collision exceeds V_0 , regardless of its direction with respect to the line of centers, it is found that the rate is given by $Ze^{-E_0/RT}(1+E_0/RT)$. Since in actual cases E_0/RT is about 40, the form of this equation is not experimentally distinguishable from a simple exponential, though of course the predicted rate, for an experimentally determined temperature coefficient, is rather larger. This latter mechanism has been considered recently by Fowler² from the standpoint of persistence of velocity;³ he has concluded that if reaction were to occur at every collision the number of high velocity molecules present in the gas would fall far below the Maxwell quota, so that the rate of reaction would be substantially less than that calculated; if the mechanism of any actual second order reaction were of this simple type, and if the theory were subject to the correction suggested by Fowler, then we should expect the rate to be very considerably increased by the addition of an inert gas, which would tend to maintain the Maxwell quota, and an effect of this kind has not been observed.

* National Research Fellow in Chemistry.

¹ See, for example, Tolman, *Statistical Mechanics*, (1927) p. 272.

² R. H. Fowler, *Statistical Mechanics*, (1929), p. 461.

³ Jeans, *Dynamical Theory of Gases*, (1925), pp. 260, 275, 312.

It seems, however, that when the molecular masses are nearly equal Fowler's correction is actually inappreciable; qualitatively this is so because in most of the collisions with relative velocity of V_0 or more, each of the colliding molecules has velocity of about $\frac{1}{2}V_0$; hence if reaction did not occur, each of them would leave the collision with velocity about $\frac{1}{2}V_0$, and, since this is very much greater than the mean velocity of all the molecules, in the vast majority of cases each of them would next collide with a slower molecule; at such a collision the relative velocity could not be greater than V_0 , so that reaction could not occur. Fowler has written, "A certain proportion of collisions with relative energy more than ξ will concern at least one molecule whose last collision was also one of the same class. This is the phenomenon of the *persistence of velocities*." This, however, is not exactly what Jeans has meant by the term; he has taken as a measure of the persistence the ratio of the expected component of velocity after the collision in the direction of the original velocity to this original velocity, and found for this ratio a value of about 40 percent. Fowler is interested not in this, but in the value of the proportion mentioned in the preceding quotation, which is a very different thing.

Since an exact calculation would involve the quadrature of some rather cumbersome integrals, it will be considered sufficient to show that the effect in question is very small. First we notice that almost all of the collisions with relative velocity greater than V_0 have relative velocity less than $9V_0/8$; the ratio of the number which exceed this limit to the number which exceed V_0 is about $e^{-17E_0/64RT}$, which is of the order of 10^{-4} .⁴ We shall use the methods given by Jeans.⁵ Instead of the three velocity components for each of the two molecules which are involved in the collision, we take three for the center of gravity, and three for the relative velocity. When we do this, we find that, both before the collision and afterwards, the relative velocity of each molecule is about $\frac{1}{2}V$. Jeans' treatment shows that the motions of the centers of gravity of the various collision complexes obey the Maxwell law for molecules of the appropriate mass, and that there is no correlation between the relative velocity of the collision and the velocity of the center of gravity of the colliding molecules. Since this is so, we can calculate the chance that the relative velocity of the center of gravity and the next molecule with which either of the original ones will collide shall exceed any specified value. We have seen that only in a negligible fraction of the collisions which concern us will the relative motion of the center of gravity of the colliding molecules and either of the molecules exceed $9V_0/16$. Now it is plainly necessary (though not sufficient), in order for the relative velocity of the next collision to exceed V_0 , for the relative velocity of the colliding molecule and the center of gravity of the two original molecules to exceed $7V_0/16$. This chance is easily calculated as about 10^{-3} . Hence we may state confidently that the proportion in which Fowler is interested is less than one in a thousand, and may be neglected. A similar treatment can be given for the case that the relative velocity along the line of

⁴ In all the following calculations, the value 40 will be used for E_0/RT .

⁵ Jeans, reference 3, p. 35.

centers must exceed a critical value for reaction to occur. Hence the simple expressions $Ze^{-E_0/RT}$ and $Ze^{-E_0/RT}(1+E_0/RT)$ are the correct rate expressions for the mechanisms which have been described when the molecular masses are nearly equal.

When the masses of the two molecules are very different, the situation is entirely changed, and the correction discussed by Fowler becomes of importance. Thus in a collision between a molecule of hydrogen and a molecule of iodine, where the ratio of the masses is about 127, the hydrogen contributes practically all the velocity of the collision; in a large fraction of all the collisions with relative velocity greater than V_0 , the hydrogen molecule itself has a velocity greater than this value, and can be expected to produce another collision of the same type if it survives the first one. The correction would be most important when the concentration of hydrogen was much less than that of iodine; then hydrogen molecules would have been expected to execute fairly long series of collisions with iodine, all with relative velocity greater than V_0 , if the system did not react; the reaction mechanism which has been postulated would cut off these series at the first member, and the rate would therefore be much less than that given by the naive calculation. There is no experimental evidence for such behavior, which indicates either that this is not the mechanism of the reaction or that if it is, then reaction occurs only at a small fraction of the collisions for which the energy condition is satisfied.

With regard to the question of the actual mechanism of second order reactions, the writer does not believe that either of these simple mechanisms is correct. It seems likely to him as it does to Fowler also, that translational, vibration, and rotational energy must all be considered, and that in most cases the effective target area for reaction will be small compared to the kinetic theory cross-section.

YOUNG'S MODULUS DETERMINED WITH SMALL STRESSES

BY DAROL K. FROMAN

RYERSON PHYSICAL LABORATORY, UNIVERSITY OF CHICAGO

(Received December 19, 1929)

ABSTRACT

An interferometer method similar to that used by E. Grüneisen was used to determine the extensions of metallic rods of brass, steel, copper, aluminum and nickel under small stresses. The largest stresses applied were considerably less than those usually used in commercial testing. For the substances examined Young's Modulus was found to increase very rapidly as the stress increased from zero, reach a maximum at a comparatively small stress, and then to decrease almost exponentially to the ordinary value. The annealing of the rod may be connected with this divergence from Hooke's law with small stresses, as slight differences were found on reannealing some of the rods used.

IT HAS been known¹ for some time that the value of Young's Modulus computed from the velocity of weak longitudinal vibrations in rods was appreciably higher than that obtained by ordinary static methods. The differences expected in the adiabatic and isothermal moduli² are small compared to those found experimentally by dynamic and static methods, although values found by these methods are often quoted as the adiabatic and isothermal moduli respectively.³ Therefore it was decided to measure the elasticity statically at small stresses, comparable with those in a sound wave. Following E. Grüneisen⁴ an interferometer was used to determine the strain.

In Fig. 1 the rods *A* are under test and the plates *B* are fixed to their ends. There is a universal joint at the point *C*. *G* and *H* are plates with holes and lock screws to clamp them to the rods. The holes are bevelled so that contact with the rods *A* can be made at one point only. By means of rods *P* the plate *G* supports another plate *E*, having a circular hole in its centre under which is supported a three-quarter silvered mirror *T*. The plate *H* has three leveling screws supporting a plate *Q*, on which is placed the other interferometer mirror *R*, similar to *T*. *N* is a right-angled prism held in position by a fixed external support and *L* is a mirror also supported from the outside. *S* is the source of light, a mercury arc, used with a filter *F*.

Monochromatic light is incident on *L* and reflected through the partly silvered mirrors to *N*, which totally reflects it to the telescope *M*. The telescope is adjusted for parallel light and circular interference fringes can be produced by making the mirrors *R* and *T* parallel with each other. The telescope is equipped with an eye-piece having both movable and fixed cross

¹ R. J. Lang, Proc. Roy. Soc. Can. 16, 163 (1907). G. W. Pierce, Am. Acad. Proc. 63, 1 (1928). E. Grüneisen, Ann. der Physik 22, 801 (1907).

³ E. Grüneisen, reference 1, p. 843.

⁴ E. Grüneisen, reference 1, p. 826.

hairs. W is a scale pan attached to the center of the lowest plate by means of a universal joint not shown in the diagram. As weights are applied at W the rods A stretch, the mirrors separating by the extension in the length from G to H . This causes the fringes to move out from their center. Three vanes not shown in the diagram are clamped to the bottom plate. These move in an oil bath to damp the motion of the apparatus after the application of a weight at W .

Measurements were made by taking the diameters of two successive fringes in the arbitrary units of the screw attached to the movable cross hair. Then a weight was applied to W and the number of fringes passing the cross

Fig. 1. Diagram of interferometer.

hairs counted. The diameter of the fringe which remained between the positions previously occupied by the two fringes measured was then taken. If readings were taken on fringes further from the center than the fourth or fifth, no appreciable error was introduced by taking the fractional fringe shift as proportional to the displacement over the width of one fringe. Thus if d_1 and d_2 be the diameters of two successive fringes, and, on the application of a weight, n fringes and a fraction pass the cross hairs, if d_3 be the diameter of a fringe occupying a position between d_1 and d_2 , then the fringe shift is $n + (d_3 - d_1)/(d_2 - d_1)$.

Since a shift of one fringe is caused by a motion of the mirrors R and T of one-half wave-length, the extension in the part of the rods from G to H can be computed, and Young's Modulus found in the usual way by dividing the stress by the strain.

Care was taken to keep the apparatus at a nearly constant temperature as the difference in the lengths of the rods P and A produces a different thermal expansion. The two sets of rods must be of the same material, also, so that their thermal expansion coefficients will be equal. It was found that if one set were of brass and the other of steel, temperature changes of one degree

Fig. 2. Curves of Young's Modulus.

per hour were quite sufficient to invalidate the results since it required two or three minutes to take a reading.

After a reading was taken the weight was removed and the diameters of the fringes checked to see if the rods had returned to their original lengths. if they had not, the reading was thrown out. It was found quite easy to measure the displacement of the mirrors to one two-hundredth of a wave-length.

The stress on the rods was adjusted to any desired value by applying weights at W and the elasticity measured by applying a small additional

weight and measuring the shift in the fringes. The stress was computed from the sum of the original weights at W , one-half of the small additional weight and the weight of the parts of the apparatus supported by the rods including one-half of their own weight.

In this way Young's Modulus was determined for five materials at various stresses. The rods used were about 40 cm long and 0.95 cm in diameter. In Fig. 2 curves of Young's Modulus against stress are plotted for the various materials.

Professor Huntley of Armour Institute, Chicago, kindly determined Young's Modulus for two of the specimens at three very much higher stresses than it was possible to use with the apparatus just described. The rods used were cut from the same piece as the ones tested with the interferometer. These values are the three with largest stresses plotted in Fig. 2 for steel and brass, respectively. By means of Kundt's tube the velocity of sound was measured in each material. The air in the tube was carefully dried and Young's Modulus, E , calculated from the relation

$$v = \sqrt{E/d},$$

where v is the velocity of sound and d is the density. The values obtained by this method are given in Table I.

TABLE I. *Young's Modulus as determined from velocity of sound.*

Material	$v(\text{cm/sec})$	$d(\text{gm/cm}^3)$	$E(\text{dynes/cm}^2)$
Brass	3.63×10^5	8.45	11.1×10^{11}
Steel	5.15×10^5	7.81	20.75
Copper	3.89×10^5	8.61	13.01
Aluminum	5.155×10^5	2.70	7.19
Nickel	4.905×10^5	8.82	21.25

For two of the materials rods were excited into longitudinal vibrations at various frequencies up to 17000 per second, by a method described by Boyle and Lehmann.⁵ The rods were cut in half and each glued, end on, to a thin piece of quartz cut with its faces perpendicular to an electric axis. This constituted a parallel-plate condenser which was connected in parallel with the variable condenser in the tank circuit of an ordinary five watt radio oscillator. Then the faces of the quartz disc were vibrated longitudinally by the piezo-electric pressures and the frequency of the electric oscillations varied until the rods came into resonance. If this frequency were in the audible range of frequencies the rods gave off a distinct sound. A precision wave-meter was used to determine the frequency of the Hertzian oscillations which was, of course, the frequency of the mechanical vibrations of the rod. In agreement with Professor Pierce,⁶ this was found to be constant at all of the frequencies tried and the same as that given by Kundt's tube, although the stresses were probably much smaller.

⁵ Boyle and Lehmann, Trans. Roy. Soc. Can., Sect. III, Vol. XIX (1925).

⁶ Pierce, Am. Acad. Proc. 63, 40 (1928).

A set of steel rods were annealed in an electric furnace and the tests again carried out. Young's Modulus was found to be slightly higher for each value of the stress that it was previously. Otherwise the behavior was exactly similar.

From these results it appears that Hooke's Law does not hold exactly for very small stresses but that Young's Modulus has a maximum at some small but finite stress. The elasticity decreases rapidly to the ordinary value as the stress is increased from this value and decreases even more rapidly as the stress is decreased from the point of maximum elasticity. It will be noted that Young's Modulus determined from the velocity of sound is somewhat lower than the values from the interferometer method but higher in the cases of brass and steel, than the values obtained with large stresses.

In conclusion the author wishes to acknowledge with thanks the assistance given by Professor Huntley of Armour Institute, mentioned above, and to thank Professor Dempster of this Laboratory for his untiring interest in the problem and his many very valuable suggestions.

ROCHELLE SALT AS A DIELECTRIC

BY C. B. SAWYER AND C. H. TOWER
THE BRUSH LABORATORIES, CLEVELAND

(Received November 6, 1929)

ABSTRACT

Both saturation and hysteresis appear in Braun tube oscillograms made at various temperatures with a condenser whose dielectric consists of Rochelle salt slabs cut perpendicular to the *a*-axis. The dielectric constant for such slabs may reach a value of 18,000. Curves are also given, showing the variation in mechanical and electrical saturation with temperature. These correspond in only a general way to the piezoelectric constant's variation with temperature. Certain marked peculiarities are noted in the resulting mechanical deformation when Rochelle salt is excited with alternating potentials. Clear Rochelle salt half-crystals have been produced up to forty-five centimeters in length.

THE remarkable physical properties of Rochelle salt, the most piezoelectric active of all crystalline substances, have been reported by other authors.¹ Comparatively small plates and few crystals were used in their determinations.

Work at this laboratory has been carried on for a number of years on Rochelle salt with a view towards commercialization. It has, therefore, been necessary to produce large clear crystals in quantity. Clear, flawless half-crystals are grown up to 45 cm in length and 2 kg in weight.

The dielectric strength and insulation value of plates from such crystals is very high. Many hundreds of plates (mostly perpendicular to the *a*-axis of the crystal) have been produced and their electrical properties measured. Thus a Rochelle salt plate 4.75 mm thick shows a dielectric constant of 18,000 when tested at 15°C at 60 volts 60 cycles alternating current. The highest previously reported value which has come to the attention of the authors is about 1380.² An air condenser of area and capacity equal to that of the crystal plate would have a plate separation of only 0.00475 mm, if 1380 be taken as the crystal dielectric constant; and 0.000262 mm (0.0001") if 18,000 be taken. It is thus evident that a comparatively thin layer of cement or dehydrated Rochelle salt between the body of the crystal and the foil electrode will introduce a very large error in the determination of the dielectric constant. Any adhesive such as balsam in xylol, Japan Gold size, or beeswax dissolved in benzol with a small addition of rosin, may be used in dilute solution for attaching the foil. It is important, subsequently, to

rub down the foil very thoroughly to bring it as close to the crystal surface as possible.

A series of Braun tube oscillograms was obtained. For this purpose, and for all other results reported in this paper, a crystal plate was employed measuring about $8.5 \times 5.5 \times 0.5$ cm, cut with its plane perpendicular to the

Fig. 1. Schematic connection of Braun tube. Capacity of crystal plate 0.004 to 0.2 Mf; of C 0.7 Mf. $R_1 = 0.45$ megohms; $R_2 = 3180$ ohms; $R_3 = 31800$ ohms.

a-axis, and its long edges parallel to the c-axis. All measurements and oscillograms were carried out with 60 cycle current from the power lines. All vertical deflections are on the same scale as in Fig. 2.

Fig. 1 shows the connections employed with the Braun tube for obtaining crystal oscillograms. At the left is a resistance acting as a voltage divider. To the right is the crystal plate under test, connected in series with a con-

Fig. 2. Oscillograms of crystal plate, free and restrained. Temperature 15° C; frequency 60 cycles per sec.

denser giving voltages proportional to the charge on the crystal. The resulting oscillograms, such as shown in Fig. 2, have ordinates proportional to crystal charge and abscissae proportional to applied voltage.

Fig. 2 shows comparative oscillograms of a plate when entirely free, and of the same plate restrained by cementing it between two thick aluminum

plates, thus very largely precluding mechanical motion due to piezo-activity. The left-hand vertical pair is for 387 peak volts per cm; the right-hand vertical pair is for 1161 peak volts per cm. The upper pair is unrestrained; the lower pair is restrained. Dielectric constants calculated from these oscillograms show exceedingly interesting and suggestive values: from the left-hand oscillogram (restrained plate) about 430; from the left-hand oscillogram (free plate) in the saturated range about 330; from the same oscillogram for a complete cycle, excluding saturation range 10,500; and for maximum instantaneous value not less than 200,000.

Such enormous values of the dielectric constant in connection with less efficient foiling of the crystal plates, may account in part for the previously observed storage battery effect. Supplementary tests indicate that little

Fig. 3. Hysteresis and saturation of Rochelle salt plate II. Potential gradient in dielectric 387 (peak) volts per cm; frequency 60 cycles per sec.

change in the value of the dielectric constant is to be looked for as a result of improvement in foiling. In these supplementary tests, electrodes of saturated Rochelle salt solution were used and results did not differ significantly from those obtained from a carefully foiled plate. Moreover these large values of the dielectric constant of Rochelle salt have been observed in many hundreds of plates of various dimensions from many different crystals. Determination of the dielectric constant was usually made by applying 112 volts of 60 cycles alternating potential to the free crystal plate and noting the resulting current. In addition, circuit resonance and condenser substitution methods served to check this first method, all three giving results in substantial agreement.

Fig. 3 comprises a series of comparative oscillograms made from the same crystal plate at different temperatures as indicated. Proceeding from top

left to bottom right it is evident that as the temperature is decreased both the voltages and charges required for saturation greatly increase. So also do the areas of the hysteresis loop. Here again the method of applying the foil electrodes to the crystal is of great importance as the shape and area of the loop will vary somewhat with this factor.

All of the oscillograms were made with the greatest care. A second crystal plate gave results identical with the first. Two other plates of the same dimensions as before but with their long edges cut at 45° to the *c*-axis, showed no essential differences in the derived oscillograms. Though no special humidity precautions were observed, the resistance of the plates, at 100 volts constant potential, never fell below many megohms.

Fig. 4. Temperature variation of saturation effect and piezoelectric constant.

If a standard plate—its long edge being cut parallel to *c*-axis—is electrified with an alternating potential, it will be deformed and such deformation can be observed and measured conveniently with a microscope. For the results shown in Fig. 4, one short edge of the plate was cemented to a large lead block and various values of 60 cycle potential were applied to the electrodes. The alternating motion produced under these conditions lies in the plane of the plate and is perpendicular to the *c*-axis. The relation between total deformation and electrification is shown for various temperatures.

Saturation is again in evidence and saturation values again increase greatly with decrease in temperature. Keeping close pace with it is the voltage required to produce saturation. But it is very noteworthy that considerable voltage must be applied before the crystal shows appreciable deformation.

Fig. 5 shows the close relationship existing at different temperatures between: 1st, volts per cm required for mechanical saturation; 2nd, the energy loss per cubic centimeter per cycle; 3rd, the charge per cubic centimeter required for electrical saturation. Though not shown in this figure, these curves are followed closely by those of the voltage required for electrical saturation and of the deformation at mechanical saturation. No determina-

Fig. 5. Properties of Rochelle salt at various temperatures.

tions of the piezoelectric constant were made, but Valasek's³ most recent curve of the temperature variation of the piezo-electric constant is included for the sake of comparing temperature variation of this property with those of the others.

It has been the great privilege of the authors to carry on this work begun under the very able leadership of the late Charles F. Brush, Jr.

SEDIMENTATION EQUILIBRIA OF COLLOIDAL PARTICLES*

BY NORRIS JOHNSTON AND LYNN G. HOWELL**
CALIFORNIA INSTITUTE OF TECHNOLOGY, PASADENA

(Received December 9, 1929)

ABSTRACT

The purpose of this work was to find the distribution law of colloidal particles for sedimentation equilibrium in large cells, in which uniform concentrations had been observed by Burton, Porter and Laird. We took great care to eliminate effects which might prevent an equilibrium state. Gold particles prepared by the Zsigmondy nuclear method were allowed to settle several days in a quartz cell in a carefully controlled thermostat bath. The steady state was determined by taking visual ultra-microscopic counts on different days. The La Place-Perrin exponential law of distribution was found to hold as demanded by the kinetic theory.

INTRODUCTION

UNTIL recent years it seemed quite well established that colloidal particles obey in their Brownian movement and related phenomena the simple laws of the kinetic theory when no forces operate between the particles. Thus, in the early work on sedimentation equilibria with colloids in a gravitational field, Perrin¹ and Westgren² found results in agreement with the familiar La Place-Einstein distribution law, which the molecules of the atmosphere obey; namely:

$$\log n = \log n_0 - Nvg h(\rho_1 - \rho_2)/RT.$$

In this equation n is the concentration of particles at the height h above a given point of reference, n_0 is the concentration of particles at the reference point, v is the volume of a particle, ρ_1 is the density of the particles, ρ_2 is the density of the medium in which the particles are dispersed, g is the gravitational acceleration constant, R is the gas constant and T is the absolute temperature. Each of the two above-mentioned men used cells constructed of microscope slides and cover glasses, the depth of the cells used by Perrin being in general about 0.1 mm. The very careful work of Westgren, who observed through ranges as great as 1.1 mm in thin cells of presumably much greater depth than the range of observation, yielded a value of N which checks very closely the accepted value.

* This paper contains results obtained in an investigation on the La Place-Perrin Law of the Distribution of Suspensions listed as Project No. 34 of the American Petroleum Institute Research. Financial assistance in this work has been received from a research fund of the American Petroleum Institute donated by Mr. John D. Rockefeller. This fund is being administered by the Institute with the cooperation of the Central Petroleum Committee of the National Research Council.

However, later workers in the field of colloids noticed that the particles in larger containers often remained in suspension over long periods of time without any apparent sedimentation. This seemed to be in contradiction with the La Place-Einstein law and investigations on distributions in sols five millimeters or more in depth were carried out by Burton,³ Porter⁴ and Laird,⁵ who reported a uniform distribution throughout the greater portion of the sol. In attempts to explain such a distribution, Burton suggested the existence of electrical forces acting between the particles while Porter assumed that his sol was so concentrated that the osmotic pressure of the colloidal solution no longer followed the simple law of dilute solutions; in other words, he introduced a volume term which acts like the b in van der Waal's equation. Although Porter introduced the b term arbitrarily, he suggested that if it should have a physical significance, in order to get the requisite size he must assume a concentration of the liquid upon the particles of the suspension. Others have suggested that the apparent contradiction might be due to insufficient precautions in the eliminating of convection or insufficient time in waiting for the attainment of the equilibrium of colloids in deep cells. Kraemer⁶ has made a very illuminating discussion of the whole field, so that it is hardly necessary to present a great amount of critical detail.

At this point, it might be well to mention that Rinde⁷ has determined the equilibrium distribution of gold colloids in a high centrifugal field produced by an ultra-centrifuge. The range shown in his plot extends over a distance of more than three millimeters and although the exponential law seems to hold in a layer about 0.5 mm thick, there is a slight deviation from this law in the remainder of the distance.

Since some knowledge of the electrical nature of colloids had already been gained from the study of electrocapillary phenomena, the possibility of forces acting between colloidal particles in such a manner as to become manifest in sedimentation equilibria was of great interest. In fact, the possibility of any factor which would upset the La Place-Einstein law seemed very important for the understanding of all phenomena in which finely divided matter is in contact with liquid. Thus, it seemed worth while for us to attack the problem of sedimentation equilibria in deep cells taking great care to eliminate spurious effects, which might account for a uniform distribution, in particular to avoid convection currents in the sol, to prepare colloids with little variation in size, and to wait a sufficient time for equilibrium to be attained.

EXPERIMENTAL WORK

In our work, we used gold sols enclosed in a cell 8.3 mm in height. This cell was constructed of quartz which is much more insoluble in water than glass.

It is important not to pollute the sol since gold sols are quite sensitive to electrolytes as regards stability. The colloidal solution was allowed to settle undisturbed for several days inside a thermostat system which was capable of holding the temperature constant to within a few thousandths of a degree Centigrade. It was necessary that temperature gradients, which cause disturbing convection currents in the cell, be avoided. The distribution curve was then found by taking visual ultra-microscopic counts at successive levels within the cell's height. The thermostat control was so little affected by the heat from the arc and the observer during the period of observation that there was a temperature rise of only a few thousandths of a degree Centigrade. Thus, the distribution could be determined and compared on different days.

A cross section of the cylindrical quartz cell is shown in Figure 1.

Fig. 1. Cross section of cylindrical quartz cell.

The vertical wall was made of tubing about 8 or 9 mm in inside diameter, the ends of which were ground in order that flat plates could be fused on to form the top and bottom of the cell. The two small L-shaped tubes were sealed into opposite sides of the tubing in order to make possible cleaning and filling of the cell. After the filling with colloidal solution, these side tubes were closed with sealing wax as shown in the diagram.

A great amount of effort was spent on the phase of the problem having to do with temperature control. In the final system, the cell was clamped inside a trough well insulated thermally inside the wooden case marked *C* in the photograph in Figure 2. The cell was immersed in a stream of water, pumped through the trough from a large thermostat tank whose dimensions were 16" \times 18" \times 27". The connections between the trough and the tank were made inside the insulating material shown in the lower left hand corner of the photograph. The temperature of the water in the trough was obtained by means of the Beckmann thermometer *B*. A view of the assembled apparatus is shown from the opposite side in the photograph in Figure 3, in which the tank is marked *T*. The water was kept in turbulent motion in the tank by means of a large stirring propellor which was rotated by the motor as seen in the photograph. Immersed in this tank was a thermostat regulator made of glass tubing filled with carbon tetrachloride, which has a high thermal coefficient of expansion. This regulator operated a relay to the heating element by means of a vacuum tube circuit mounted on the top of the tank near-by the

relay. With this circuit practically no current flowed through the mercury contact in the regulator.

In Figure 3 a part of the optical system can be seen mounted on the sturdy wooden frame to the left of the tank. The entire optical system was built on the heavy metal carriage *L*. The colloidal solution was illuminated by means of the carbon arc *A*, the light from which was passed through the copper chloride absorption cell *H* in order that the beam which was transmitted should have little heating effect. Next the beam was passed through a paraboloidal condensing lens, a 16 mm microscope objective and a glass window in the trough immediately in front of the cell. The beam was transmitted into the cell through the curved wall and was brought to a focus in a fairly small pencil inside the cell. Observations were made with the microscope *M* in Figure 2, suspended on the carriage directly above the cell. This microscope consisted of the vertical tube made of Bakelite for thermal insulation, an objective with a focal length of 16 mm immersed in the water of the trough, and a hyperplane eyepiece containing a scale divided into squares, one of

Fig. 2.

Fig. 3.

which was divided into smaller squares. The focal plane of the microscope fell within the pencil of light inside the cell and counts of the numbers of colloids inside squares could be made. Various levels in the cell could be observed by raising or lowering the entire carriage by means of four screws upon which were mounted divided heads. Two of these screws *S* can be seen in Figure 3. Large changes in height could be read from the screw-heads while small changes could be read by means of the cathetometer *K*.

Gold sols were prepared by the Zsigmondy nuclear method,⁸ which was used by Westgren and is perhaps the most highly recommended for obtaining particles closely uniform in size. The La Place-Einstein law is, of course, valid only for particles having a definite radius and a definite mass. The nuclear sol was formed by the reduction of gold chloride by phosphorus dissolved in ethyl alcohol. The nuclei were enlarged in two steps by the reduction of gold chloride upon the particles by means of hydrogen peroxide (30 percent). The sol upon which observations were made was obtained by diluting this gold sol. In this preparation, it was highly important to obtain water low in both sus-

⁸ Rinde, Diss. Upsala, p. 25 (1928).

pendent matter and electrolyte content. A special still was constructed which employed the partial condensation of steam from water treated with potassium permanganate and potassium carbonate. The steam was passed through a settling chamber and a tin condensation tube. The water was collected in a Jena glass bottle.

RESULTS

We shall show distribution curves for two different sols which contained particles approximately the same size, but were different in initial concentration. The temperature control for the more dilute sol was not as good all of the time as might have been desired. Also, one or two small bubbles were observed in the top of the cell when it was removed. However, the consistency of

Fig. 4.

the results would indicate that no serious disturbances were set up, as one may see in Figure 4 where logarithms of concentration values are plotted as ordinates, and in Figure 5 where the same concentration values are plotted in the ordinate direction. Each of the points shown is taken from 50 counts with the exception of the two lowest points marked with circles which are taken from 25 counts. The points marked with dots were taken after about 3 days of sedimentation while the points marked with circles were taken from the same sol after about 5 days. The concentration at the end of 5 days in the upper regions was roughly one-half percent of the highest concentration observed. Such a value is even lower than the lowest point shown, so that the distribution curve lies very close to the zero axis in the upper part of the cell. This portion of the curve was somewhat higher as observed at the end of three days of sedimentation, the concentration near the top being almost as great as that shown by the lowest point plotted and also being greater than the concentration in an intermediate region. This latter would indicate that there might

have been a slight disturbance in the upper regions which was of practically no consequence in the immediate neighborhood of the bottom, where, after all, the bulk of the particles in which one is interested was located. The impor-

Fig. 5.

tant fact is that a steady state was reached and the distribution of the particles in this state was exponential. The slope of the curve shown in Figure 4 is 87; the temperature was 26.5°C.

Fig. 6.

The second sol which was of higher concentration was unusually stable and the cell was allowed to remain in the thermostat for a period of about two

weeks. During the first three days of sedimentation, the two extreme temperatures observed differed by only 0.005°C , so that for long periods of time, the temperature was scarcely seen to vary on the Beckmann thermometer. The temperature was maintained at 26.5°C . Curves I to V shown in Figure 6 were obtained after sedimentation periods of 3, 5, 8, 9, and 10 days respectively. At each level marked by a point, a total of 50 counts was taken. It should be mentioned that the counts were made with quite a little difficulty due to the scattering of light near the bottom of the cell (in a large measure from the dense layer of colloids), the shifting of the light pencil due to changes of the arc, and the psychological factor attendant with such counts. However, the slopes of the curves are fairly consistent and the average is 96. The relative displacements of the curves were perhaps in a large measure due to the experimental error in locating the bottom with respect to the points, although it is not certain that actual shifts of the distribution did not occur. Certainly, it is more difficult to avoid slight disturbances in the regions observed in Figure 6 than those in Figure 4 since these regions are further removed from the damping surface at the bottom. In any case, whether the displacements were real or not, the effect was certainly of no prime importance as regards the distribution law which is seen to be exponential in character. In this solution the colloidal particles became remarkably scarce in the upper regions. On the ninth day, the concentrations observed in the main body of the sol were of the same order as those observed on the fifth day for the other sol, and thus were relatively slight since the latter sol was much the less concentrated of the two initially. This scarcity of particles is important since the distribution curve should approach the zero axis very rapidly upwards. The slight upward displacement of the experimental curve above the theoretical curve in the upper regions might be due to the lateral diffusion of particles into the cell from the side arms, the presence of particles differing in size or density from the bulk of the gold particles, and perhaps the presence of undetected slight movements of the sol.

DISCUSSION

As has been pointed out by others, it is likely that both Burton and Porter did not take sufficient precautions against disturbing convection currents. Burton and Bishop,⁹ working with copper colloids, used a large tube 94 cm long without much care in this respect. Burton and Currie,¹⁰ working with gamboge, arsenious sulphide, Bredig copper and Bredig silver colloids, repeated the work using 145 cm tubes immersed almost completely in a thermally insulated bath. They state that this bath was stirred "from time to time" and that the temperature of the room varied slowly over a range of 7°C during the period of four months of sedimentation. It is very doubtful if such conditions were satisfactory. Porter and Hedges¹¹ working with gamboge particles, fractionally centrifuged to obtain uniformity in size, reported that

⁹ Reference 3.

¹⁰ Reference 3.

¹¹ Reference 4.

although the distribution was uniform in the greater portion of their cell's height, the concentration diminished near the top as the top was approached. We, also, found a similar distribution in our early work when there were disturbing currents. In addition, however, we found an increase in concentration near the bottom. It is unfortunate that Porter did not investigate the region in the immediate neighborhood of the bottom, although it is quite surprising he found no appreciable increase in concentration in the lowest level he reached. Barkas¹² working under Porter stated that convection currents were quite a disturbing factor in his work. It is very easily seen how there could be a settling of particles in the neighborhood of a surface even though convection currents were stirring up the particles in the central portion of the sol since the frictional drag at the surface would prevent appreciable currents from being set in motion in that neighborhood. Thus one might expect to find the diminishing concentration near the top.

Then there is the phase of the problem which concerns the time necessary for sedimentation equilibrium to be attained. The theoretical work on sedimentation has been done by Mason and Weaver¹³ and Fürth.¹⁴ Weaver¹⁵ laid down the general rule that equilibrium should be attained within the time that it takes a particle to settle twice the depth of the cell according to Stokes' law. Later Fürth¹⁶ stated more rigorously that the necessary time is proportional to the cell depth when RT/NXl is large, and proportional to the square of the cell depth when this quantity is small. In this expression, which is called α by Mason and Weaver, X is the resultant gravitational force acting on the particle and l is the cell depth. Fürth estimated that it would take a number of years for equilibrium to be attained in Burton's work. As already stated, the time of sedimentation was only four months. It must be mentioned that the whole problem in Burton's case is very indefinite since he did not use particles of uniform size. As pointed out by others, since Porter does not state the length of time allowed for sedimentation, it is quite possible that he did not wait long enough for equilibrium conditions. Fürth pointed out the similarity between Porter's curve and the theoretical transient state curve. In our work, we have calculated the time necessary for a gold particle to settle twice the height of the cell for the sol of Figure 4, taking the slope of the equilibrium curve to be 87. The value of the radius obtained from the La Place-Einstein equation is 3.6×10^{-6} cm. From Stokes' law, the time of settling a distance of twice our cell depth, or 1.66 cm is 76 hours or about three days. A steady state was apparently reached in our work in about 3 to 5 days. Thus, it seems that the Weaver rule holds roughly in our case. Our value of α is 0.014.

Burton¹⁷ explained the uniform distribution curve by assuming that the colloidal particles are electrically charged and repel each other. Porter

¹⁷ Burton, "The Physical Properties of Colloidal Solutions," p. 87.

criticised this theory by stating that the particles would tend to move to the walls of the containing vessel in such a case.

Burton¹⁸ also suggested that the settling of colloids may be prevented by Brownian movement and defined as the "critical radius," that radius for which the particle is displaced by Brownian movement in one second the same distance through which it would fall in one second according to Stokes' law. Particles with radii smaller than this so-called critical radius would remain in suspension without sedimentation. Now, of course, as Kraemer has pointed out, Brownian movement takes place in no favored direction and it is obvious from our results that settling did take place. The critical radius of gold is several times our radius since Burton gives 28×10^{-8} cm as the critical radius of platinum, which is heavier than gold.

Porter has suggested that his results were due to the fact that his sol was no longer dilute. His concentration of gamboge particles was of the order of 10^7 per cc. From our work, the concentration represented by the highest point plotted in Figure 5 is of the order of 4×10^8 per cc. Porter's value of concentration seems far too low to justify his assumption of a concentrated sol, especially in comparison with the concentrations used by the earlier workers.

Porter has also suggested that there are three distinctive regions in a colloidal solution: the Gibbs layer located very close to the surface, the "Perrin layer" in which the colloids are distributed exponentially in a layer a fraction of a mm in thickness near the top of the vessel, and finally "a layer of one or two millimeters' thickness (in the particular cases studied in this paper), in which a further change of concentration occurs which can not be calculated in the way adopted by Perrin." The third region is close above the principal part of the sol in which the concentration is constant. From our results, we have concluded that in the case of particles more dense than water in deep cells the particles are distributed in a "Perrin layer" extending from the bottom upwards. Whether this layer extends appreciably up through the main body of the sol should depend upon the height of the vessel, the radius and the density of the particles, and the initial concentration of the particles. Certainly if one should look for an anomaly in the distribution law due to high concentration, the logical region to investigate is that near the bottom of the cell where high concentrations may be obtained. In fact Constantin¹⁹ working with high concentrations of gamboge particles found a deviation from the exponential law in the lower portion of the range which he investigated.

In conclusion, it seems that the work on colloidal suspensions leading to a uniform distribution was very likely not free from spurious effects and that there is no change in distribution law in increasing the height of a cell. Such a conclusion is certainly in harmony with the bulk of the other work related to this phase of the study of colloidal particles.

We wish to express our gratitude to the American Petroleum Institute for the funds furnished for this research, to Dr. R. A. Millikan for his interest as director of this project, to Mr. A. A. Grubb for his aid in the experimental work and to Dr. M. E. Nordberg for constructing the quartz cells.

LETTERS TO THE EDITOR

Prompt publication of brief reports of important discoveries in physics may be secured by addressing them to this department. Closing dates for this department are, for the first issue of the month, the twenty-eighth of the preceding month; for the second issue, the thirteenth of the month. The Board of Editors does not hold itself responsible for the opinions expressed by the correspondents.

Inhomogeneities in Crystals (A Reply)

Dr. R. H. Canfield¹ has published in a letter of the above title some objections to my theory of the mosaic structure of crystals. His arguments are based on a very serious misunderstanding of my considerations.² In order to clear up the case, I shall repeat here the general method which enabled me to find configurations of lower energy than that of the crystallographically ideal crystal. For the sake of an unambiguous illustration, I shall give the energy changes involved for the very specific case of an NaCl crystal.

Using the notations of loc. cit., we have $d_0 = 5.6\text{\AA}$ for the lattice constant of NaCl. The lattice constant of an isolated (100) plane "in equilibrium," which is not sandwiched in between other (100) planes, is $d = 0.94d_0$. The outline of my method for finding the configurations of low energy given in loc. cit. p. 818 is literally this.

" α) Contract (an arbitrary plane 100) II so that its spacing is changed from d_0 to d .

β) Fill the gaps which have been opened by α between the two remaining parts I and II of the crystal.

γ) Rearrange the relative position of I and II in a certain way."

If we disregard the polarizability of the atoms for a moment, then the process α involves an energy change $\epsilon_\alpha = \epsilon_1 + \epsilon_2$, where ϵ_1 represents the (negative) energy of contraction of the plane II under its own forces. ϵ_2 is the positive energy which has to be supplied in order to annihilate the energy of the plane II relative to the remaining parts I and II. It is easily seen that ϵ_2 if taken per cm^2 is approximately equal to $2\sigma = 300$ ergs where σ is the theoretically derived surface energy of NaCl. The value for $\epsilon_1 \cong -220$ ergs/ cm^2 may be obtained from curves published by I. E. Lennard-Jones and B. M. Dent³

for instance. It is $\epsilon_1 + \epsilon_2 > 0$ as Mr. Canfield justly remarks. Otherwise an NaCl crystal would fall apart.

The step β involves a negative energy change which is easily seen to be 12 percent of 2σ approximately. This yields $\epsilon_\beta \cong -36$ ergs/ cm^2 . The rearrangement γ in our specific case is a very simple process. Exchange all the positive ions with all the negative ions in part I of the crystal. This leaves the relative energy between I and the plane II unaltered. It involves, however, a small negative change of energy of I relative to II; namely, $\epsilon_\gamma \cong -20$ ergs/ cm^2 .

Finally, we have to consider the polarizability of the ions. In the ideal crystallographic configuration, the ions are in locations where the electric field strength is zero. The ions (e) of our II plane, however, are subjected to fields of the order of $E = 4e/d_0^2$ e.s.u. due to the rearrangement γ of the relative position of I and II. We therefore have lowered in this way, the energy of an ion in the II-plane by an amount $|\delta\epsilon_i| = \alpha E^2/2 = 8\alpha e^2/d_0^4$ where α is the polarizability of the ion. The average value of α for the couple Na^+ and Cl^- may be taken equal to that of Ne and A with sufficient accuracy. This results in $\alpha = 10^{-24} \text{ cm}^3$. We therefore obtain $\delta\epsilon_i = -1.8 \times 10^{-13}$ ergs/ cm^2 . As there are $n = 1.3 \times 10^{15}$ ions per cm^2 , we have $\epsilon_4 = n\delta\epsilon_i = -230$ ergs/ cm^2 . This value has in reality to be multiplied by a factor of the order of three, because of the fact that the ions in the two neighboring planes of II are also subjected

¹ R. H. Canfield, Phys. Rev. **35**, 114 (1930).

³ I. E. Lennard-Jones & B. M. Dent, Proc. Roy. Soc. A**121**, 259 (1928).

to the same high fields. In any case the, figures show conclusively that the total change in energy is $\epsilon = \epsilon_a + \epsilon_b + \epsilon_c + \epsilon_d < 0$ which verifies my general contention for the case of rock-salt.

The principle which led me to the conception of the mosaic structure might be called the *principle of the slight asymmetries in complex configuration* such as atoms, molecules, and crystals. *Indeed, due to the deformability of the atoms and molecules, nature, according to the above, definitely favors configurations which are somewhat asymmetrical.* I owe to Professor O. Stern the remark that this principle might apply to cases like $\text{H}_2\text{O} = (\text{HO}^- + \text{H}^+)$.

The trivial consideration mentioned by Mr. Canfield that under the proper circumstances, certain planes like (111) have a tendency to expand has not escaped my attention. Indeed, I have thought out its consequences long ago. One of them I have mentioned, loc. cit. p. 820, "In regard to the space groups characterizing the primary and the secondary (mosaic) structure, it must be remarked that they are not necessarily the same, etc."

In regard to the experimental evidence which we have secured so far, I can mention here only that it supports my conception of a *spacial* mosaic structure. It is not a surface

phenomenon only as Mr. Canfield seems to think. Moreover, if an indirect argument is wanted, I may mention the quantitative agreement which can be obtained on the basis of my theory with some of the important phenomena related to the *slipping strength* (not the tensile strength). For all further detailed information, I have to refer the reader to several articles by my collaborators and myself which will be published presently. A complete representation of my theory is now in preparation for the *Helvetica Physica Acta*.

Finally, I wish to make a remark in regard to the development of the theory. Mr. Canfield intimates that I had secured direct experimental (optical) evidence for the mosaic structure first, and then developed a theory "resulting in a prediction of the required phenomenon." I can only state that the exact contrary is true, inasmuch as *all* the experimental investigations at this Institute dealing with the mosaic structure have been undertaken at my suggestion to check the theoretical predictions and *all* the evidence obtained is posterior to the development of the essentials of the theory.

The Effect of Dilution upon the Raman Spectra of Nitric Acid

Photographs of the Raman spectra of dilute and concentrated solutions of nitric acid in water obtained in this laboratory last May show striking differences in the frequencies of the lines scattered in the two cases. Lines which are strong in commercial 70 percent acid become weak and ultimately disappear as the acid is diluted, and other lines, weak in the concentrated acid grow strong, reach a maximum intensity and disappear as the dilution becomes infinite. In a recent note to *Nature* (124, 762 (1929)) I. R. Rao reports similar results. As Rao points out, the effect can be attributed to dissociation. The lines which are strong in the concentrated acid and which disappear upon dilution are very probably due to the HNO_3 molecule. Those which are greatly enhanced by dilution can be attributed to the NO_3^- ion.

Four infra-red frequencies, two forming a doublet, give rise to the strong scattering in

the concentrated acid, and hence may be associated with the HNO_3 molecule. They are 618, 669, 937, and 1293 cm^{-1} . One transition, at 1034 cm^{-1} , grows enormously strong with dilution, reaching its greatest strength, approximately, in mixtures of equal volumes of water and commercial acid. Rao attributes the doublet at 618 and 669 cm^{-1} (given by him as 630 and 689 cm^{-1}) to the NO_3^- ion. On the plates obtained by the author this pair behave exactly as do 937 and 1293 cm^{-1} disappearing completely in a 25 percent solution of the commercial acid. At this dilution 1034 cm^{-1} is still of high intensity. Rao reports, in addition, a Raman frequency at 3319 cm^{-1} and attributes it to the HNO_3 molecule. No such frequency was found on the present plates. The doublet transition 618 and 669 cm^{-1} which is strongly excited by the mercury line 4358 appears only feebly excited by 4046 in concentrated acid. An

interpretation of this as a singlet transition excited by the 3650 mercury line would give a scattering frequency of 3328 cm^{-1} . It is possible that this corresponds with Rao's reported 3319 cm^{-1} transition which he attributed to the HNO_3 molecule.

The variation of the intensity of the lines with dilution is clear cut and is believed to be the second optical indication of the formation of different molecular or ionic species by the dilution of strong acids. The first was obtained years ago by Pfund (*Astrophys. J.* **24**, 19 (1906)), who observed differences in the infra-red frequencies, reflected from surfaces of fuming and dilute sulphuric acid. The

effect undoubtedly affords a new probe into the processes of dissociation in solution and will be particularly useful in cases where the strong absorption of water makes the solution opaque to the infra-red. The Raman work is being extended to salts, other acids and electrolytes, and in collaboration with Professor Ellis the infra-red absorption spectra, as a function of concentration, are being studied.

Note on Electron Scattering in Atomic and Molecular Hydrogen

The theoretical scattering formula in the paper on Electron Scattering in Atomic and Molecular Hydrogen in the *Physical Review* of September 1st, 1929, refers to the number of electrons scattered between the angles θ and $\theta+d\theta$, whereas the experimental points represent the scattering in the solid angle between θ and $\theta+d\theta$. In order to make the experimental points refer to the quantity given by the theoretical formula they must be divided by a factor proportional to the sine of θ . When this is done to the results for inelastic scattering the points are in much better agreement with the theoretical curve. But when the proper correction is applied to the results for elastic scattering the agreement with the theoretical curve is not as good as that given in the paper. The departure from

the curve at small angles is probably due to the influence of adsorbed gas on the slits of the apparatus. Some evidence of this was found during the experimental work but it was not a factor which could be accurately determined and corrected for. It would be of about the right amount to account for the observed departure at small angles. At large angles the observed scattering would differ from that predicted by the formula. The explanation of this effect is not clear, unless it is due to the scattering from molecular hydrogen. It is hoped to obtain further information on these points with an apparatus of different design.

Evidence of the Presence of Element 87 in Samples of Pollucite and Lepidolite Ores

Element 87 is peculiarly well placed in the periodic table for detection by a new and very sensitive method recently reported by us. (*Phys. Rev.* **35**, 124 (1930).) We have accordingly made a search for this element in samples of pollucite and lepidolite ores supplied by the Research Laboratory of the General Electric Company, and we have consistently found minima at points of the scale which correspond to an element of the atomic weight and the valence ascribed to eka-caesium. We have studied the substance in the chloride, sulphate, nitrate and hydroxide compounds, in each case finding the minima at points of the scale characteristic of an element of the chemical equivalent of eka-caesium. Since the same element in different compounds produces its character-

istic minima of light at different points of the scale, the fact that minima are observed in each of the four compounds at the points appropriate to element 87 affords evidence of considerable weight for its presence in the sample under test. The element appears to have several isotopes, as judged by the number of its characteristic minima. The method employed is sufficiently delicate to detect less than one part of a compound in 10^{10} parts of water. The work is still in progress.

Voltage Intensity of $\lambda 2537$ in Mercury

In a recent paper (Phys. Rev. 34, 1352 (1929)) note was made that the curve (Fig. 3) showing the relation between the voltage of the electrons and the intensity of the radiation from mercury vapor apparently was a composite of two curves, one with a maximum at about 5.5 volts and the other with a maximum at about 5.95 volts. Since the whole radiation from the beam was focused on the photographic plate it was not possible to decide whether these two maxima are characteristic of $\lambda 2537$ alone or whether at about 5.7 volts a new radiation, possibly a molecular band, was added to $\lambda 2537$. In this connection it was thought significant that in critical potential measurements under similar conditions a critical potential at 5.7 volts is always found.

The purpose of the present letter is to present results which indicate that the curve given in the paper referred to is characteristic of $\lambda 2537$ alone, and that no light of other wave-length is responsible for the appearance of two maxima in that curve.

The light from the excitation tube was

passed through a 2.9 cm path of a solution of 1 part of glacial acetic acid to 200 parts distilled water. This cell absorbed about 95 percent or more of light of wave-length shorter than 2350A and about 75 percent of light of wave-length 2537A. This would decrease any light of wave-length less than 2350A to $\frac{1}{4}$ or less of its former relative importance. A curve was taken with the cell in place and it checked the two previous runs as closely as they checked each other. This indicated that there was no appreciable amount of light of wave-length less than 2350 affecting the photographic plate.

A spectrograph was made of a monochromatic illuminator. The slit of the illuminator was removed and the beam of light from the tube was used as a slit. A special ultra-violet plate made by the Eastman Kodak Company was used to emphasize any light in this wave-length region, but no light was found other than $\lambda 2537$.

BOOK REVIEWS

Advanced Laboratory Practice in Electricity and Magnetism. EARLE M. TERRY. Second Edition, 1929. Pp. 318, figs. 175. McGraw-Hill Book Co., New York. Price \$3.00.

This is a second and somewhat larger edition of Professor Terry's well-known manual for use in a course which in many institutions is called "Electrical Measurements." The introduction a dozen or so years ago of the use of audiofrequency oscillatory currents into laboratory experiments and the development of very sensitive telephone receivers revolutionized the methods (and the theory) of the measurement of capacitance, and self and mutual inductance. The first edition of this book was outstanding in its use of these newer methods. In the new edition the number of experiments has been increased by about 25 percent, most of the new ones being on three-element vacuum tubes and oscillatory circuits. These new experiments have been so planned that they may be used in a course on radio communication. The extensive use of vacuum tubes in many types of physical measurements makes it desirable to give in our advanced laboratory courses experiments in this field. The same clearness that was characteristic of the presentation of both the theoretical and the experimental parts of the first edition is shown in the additions.

The manuscript for this edition was finished by Professor Terry before his death and the responsibilities connected with the publication were undertaken by Professor H. B. Wahlin, a colleague in the University of Wisconsin.

O. M. STEWART

The Electromagnetic Field. MAX MASON AND WARREN WEAVER. Pp. xiii+390. University of Chicago Press, 1929. Price \$6.00.

In his attempt not to discourage the student with lengthy analysis and fine reasoning the author of the average text on electromagnetism glosses over many delicate logical difficulties in a way that often proves very disturbing to the thoughtful reader. The authors of the present volume, on the other hand, have attempted to present the fundamentals of the classical electromagnetic theory with as great a degree of mathematical rigor as the subject permits, and have been exceptionally successful in achieving their objective. Their argument requires in many places the closest attention on the part of the reader, but any effort on his part is well repaid by the very much clearer understanding of the subject which he gains. The treatment is necessarily quite mathematical, and the close analysis of the subject which the authors have undertaken has necessitated a rather annoying recourse to subscripts and accents. The book is hardly one which can be recommended as an introductory text in electromagnetism but to the advanced student who is looking for a rigorous development and critical study of the subject it should prove invaluable.

The very elegant treatment of the difficult subject of dielectrics in electrostatic fields merits particular commendation. In so far as the potential theory aspect is concerned it leaves little to be desired. On the other hand the equally difficult subject of stresses in dielectrics and on conducting surfaces, which is perhaps more puzzling to the student than any other part of electrostatics, has hardly received an adequate presentation.

The authors make no attempt to develop the relation between electrodynamics and the special relativity theory, nor do they make any use of four-dimensional vector analysis. Instead of the significant three-dimensional vector notation of Gibbs they have preferred to use the parentheses, brackets, divs and curls which European writers generally employ. They have been careful to avoid any mention of lines of force either electric or magnetic, a procedure which can hardly be claimed to increase rigor while it deprives the reader of the aid of a convenient geometrical picture. A feature much to be commended is the placing of an introduction at the beginning of each part of each chapter and of a concluding paragraph at the end. In this way the reader is given an idea of the aim of each part before he enters upon

the analytical details and he gains from the conclusion at the end a perspective which he might otherwise miss.

The book is divided into four chapters each of which contains several parts. The titles of the chapters are "Coulomb's Law and Some Analytic Consequences," "The Electrostatic Problem for Conductors and Dielectrics," "Magnetostatics" and "The Maxwell Field Equations." In addition to the formulation of Maxwell's equations the last chapter takes up the activity equation, electromagnetic waves, retarded potentials, and the concept of electromagnetic mass. The discussion of the activity or energy equation is especially clear and searching. At the end of the book are a mathematical appendix on vector analysis, a formula index and a general index.

While the book contains much analysis the physics of the subject is by no means neglected and every difficult point is carefully and fully explained. The process of averaging in the case of a dielectric, for instance, is discussed in much detail with illustrations drawn from outside the subject of electromagnetism. The whole work gives every evidence of the most careful and painstaking preparation. It constitutes unquestionably the foremost critical study of electromagnetic theory in the English language.

PROCEEDINGS
OF THE
AMERICAN PHYSICAL SOCIETY

MINUTES OF THE DES MOINES MEETING, DECEMBER 30 AND 31, 1929

The Thirty-first Annual Meeting (the 161st regular meeting) of the American Physical Society was held in Des Moines, Iowa at the Hotel Fort Des Moines on Monday and Tuesday, December 30-31, 1929. The presiding officers were Professor Henry G. Gale, President of the Society, and Professor P. W. Bridgman. The average attendance was about 150.

On Tuesday morning Professor Henry G. Gale delivered the presidential address, his subject being, "The Interplay between Theory and Experiment in Modern Spectroscopy."

The annual joint session with Section B was held on Tuesday afternoon. The presiding officer was Professor Charles E. Mendenhall, Vice-President of Section B. The program consisted of the address of the Retiring Vice-President of Section B, Professor P. W. Bridgman, on the subject, "Permanent Elements in the Flux of Present Day Physics." In addition there were two invited papers, "Polarization of Matter Waves" by A. Landé, University of Tübingen (Germany), (Ohio State University 1929-1930) and "The Wave Mechanics of Collision Processes" by L. H. Thomas, University of Cambridge (England), (Ohio State University, 1929-1930).

On Monday evening, December 30, there was a dinner for the members of the Society and Section B and their friends in the Hotel Fort Des Moines, attended by seventy-five persons.

Annual Business Meeting. The regular annual business meeting of the American Physical Society was held on Tuesday afternoon, December 31, 1929 at three o'clock. A canvass of the ballots for officers resulted in elections for the year 1930 as follows:

President:	Henry G. Gale
Vice-President:	W. F. G. Swann
Secretary:	W. L. Severinghaus
Treasurer:	George B. Pegram
Members of the Council, Four	L. W. McKeehan
year term:	D. L. Webster
Members of the Board of the Physical	F. W. Loomis
Review, Three year term:	K. F. Herzfeld
	A. W. Hull

The Secretary reported that during the year there had been 261 elections to membership. The deaths of 4 members had been reported during the

year; 30 had resigned and 38 had been dropped. The membership of the Society as of December 31, 1929 was as follows: Members: 1834; Fellows: 532; Honorary Members: 6; Total Membership: 2372. The numbers are approximate because they include elections and transfers at the November and December meetings. In the year there had been a net increase of 197 members and a net increase of 12 fellows.

The Treasurer's financial report for the year 1929 was presented by the Secretary.

The Managing Editor presented the financial report for the Physical Review for the year 1929 and for the Physical Review Supplement for May 1, 1929 to November 30, 1929. The reception of the Supplement by the members of the Society and others was reported to be very gratifying. A greatly increased speed of publication of papers and letters for the Physical Review was also reported. The number of pages printed increased over last year as did also the cost per page of printing. An operating loss of approximately \$2400 in the publication of the Physical Review for 1929 was reported.

At this session the Council announced that in the week of June 16th the Society would hold a meeting at Ithaca, New York, by invitation from Cornell University. This meeting is to be of a somewhat less formal nature affording more time for discussion of the papers presented.

Meeting of the Council: At its meeting held on Monday morning, December 30, 1929, six persons were elected to fellowship, five were transferred from membership to fellowship and forty-six were elected to membership.

Elected to Fellowship: Robert d'E. Atkinson, James A. Beattie, Edward Mack Jr., Thomas H. Osgood, Hugh S. Taylor, and J. W. Williams.

Transferred from Membership to Fellowship: Gaylord P. Harnwell, Robert B. Lindsay, Harry B. Maris, Jonas B. Nathanson and E. P. T. Tyndall.

Elected to Membership: Homer G. Anderson, Soichiro Asao, Robert F. Bacher, James W. Ballard, Fred J. Beck Jr., Lowell C. Beers, Claud E. Cleeton, Howard L. Cobb, Samuel G. Cook, William F. Drea, Charles Foster, Darol K. Froman, Willard Geer, Yu Ming Hsieh, Hugh H. Hyman, Ellis A. Johnson, Matthew T. Jones, E. B. Jordan Jr., Walter H. Jordan, Louis S. Kassel, Ray W. Kenworthy, P. W. Ketchum, Jackson G. Kuhn, Frances M. Lemery, John A. Madigan, Kyuzi Matukawa, Iwao Miyake, Lawrence D. Montgomery, Herbert D. Owens, Everett R. Phelps, L. R. Philpott, Robert M. Pinkerton, Cyrus A. Poole, G. W. Presnell, W. R. Pyle, Bernhard A. Rose, Herman M. Roth, Otto Rothenstein, L. A. Sanderman, H. W. B. Skinner, Masamichi So, Roy R. Sullivan, Hisao Suzuki, Ryoza Tajime, Vernon Thornton and Tameiti Yasaki.

The regular program of the American Physical Society consisted of 32 papers. Numbers 4, 9, 16, 18, 19, 20, 22, 24, 26 and 28 were read by title. The abstracts of these papers are given in the following pages. An *Author Index* will be found at the end.

W. L. SEVERINGHAUS, *Secretary*.

ABSTRACTS

1. X-ray scattering by mixtures of organic liquids. A. WESLEY MEYER, *University of Iowa*.—The x-ray scattering curves for the following mixtures were obtained; n-ethyl alcohol—methyl cyclohexane, n-butyl alcohol—orthodimethylcyclohexane, quinoline-phenol, cyclo-hexane—tetranitromethane and phenol-water. All mixtures but the last one are totally miscible, and it is a solution with either large water content or high phenol content but is an emulsion at other concentrations, but may be dissolved by heating. The resulting curves have peaks to which Bragg's Law is applied to obtain the spacings of the molecules in the cybotactic groups. The results indicate that in every case of solution there is a single type of cybotactic group in which both kinds of molecules participate. The molecular spacing of the group is intermediate between the spacings of the pure liquids and dependent upon the number of each kind of molecule present. In the phenol-water emulsion curves, two spacings were found corresponding to those of saturate phenol water, and saturate water phenol, agreeing with the common belief that the molecules of the constituents of an emulsion do not intermingle, except in large groups, the constituents in this case being the two saturate solutions. The conclusion concerning solutions agrees with that obtained in cases of solid solutions such as alloys.

2. Dependence of viscosity in liquids upon the molecular space arrangement as shown by x-ray diffraction. R. L. EDWARDS, *Miami University* and G. W. STEWART, *University of Iowa*.—It has become possible to make a comparison between the physical condition of a liquid and its viscosity. Twenty-one octyl alcohols made under the direction of Professor E. Emmet Reid of Johns Hopkins were examined by x-rays. The "perfection" of the molecular groups were estimated by the magnitude of the secondary diffraction peaks which evidently depend upon the planar spacing of diffraction centers in the direction of the length of the molecules rather than diametrically. The coefficients of viscosity were obtained by the measurements of Professor E. C. Bingham of Lafayette College. When the OH group is in a fixed position and a methyl group of the octyl alcohol is placed in the possible positions in the molecule, the variation in the coefficient of viscosity varies in a manner similar to that of the magnitude of the secondary peak. The agreement is striking because the variations are large. The interpretation made is in accord with the obvious effects that grouping of molecules to any extent would have. The need of the incorporation of the cybotactic condition or molecular grouping in any theory of viscosity of liquids is emphasized.

3. The extent of noticeable cybotactic condition in a liquid as exhibited by triphenol-methane. G. W. STEWART, *University of Iowa*.—By means of the comparison of the chief x-ray diffraction peak of triphenolmethane in powdered crystal form with that occurring with the liquid, an approximate estimate may be made of the extent of the condition of molecular space grouping throughout the liquid. Areas of the diffraction curves were determined, the experiments being made with thicknesses of material, equal as determined by weight. It was found that the total diffracted energy in the chief diffraction peak of the first order was greater with the liquid than the crystal. Properly interpreted this means that the effective groupings of the molecules in the liquid are approximately of the same extent in the liquid as in a finely powdered crystal. Ignorance concerning the exact nature of the grouping and the structure factors prevent any quantitative comparison.

4. The structure of certain *K* series emission lines. J. VALASEK, *University of Minnesota*.—Recently, Davis and Purks have reported several new satellites near the $K\alpha_1$ and α_2 emission lines of Ni, Cu, and Mo, and $K\beta_1$ of Mo, using a double-crystal spectrometer. The writer has attempted to confirm these results in Siegbahn's laboratory, using a new single-crystal spectrometer designed by Siegbahn. With the slit 0.03 mm wide and the plate at 3 meters, the resolving power in the first order was equal to that of the double-crystal spectrometer in the first order. According to the curves given by Purks, some of the satellites should be perceptible in the first order. Microphotograms were made of the following lines: $K\alpha_1$ and α_2 of Cu, Mo, and Ag, and $K\beta_1$ of Mo. No satellites were found. Lack of time prevented observations in the second order.

5. Fine structure in K x-ray absorption spectra. BEN KIEVIT, JR. and GEO. A. LINDSAY *University of Michigan*.—The K x-ray absorption spectra of the free elements Ca, Cr, Mn, Co, Ni, Cu and Zn have been photographed and for each of these elements an extended fine structure has been obtained. This fine structure, consisting of six or seven secondary edges, extends over an energy range of some 200 volts. In every instance the element was used as the absorbing screen except in the case of manganese where it was present in the alloy manganin. Indications are that the alloy screen gives the same result as the element alone. A KCl crystal served as reflector to obtain the spectra. Additional exposures were made with copper and with zinc, using the [111] face of calcite as reflector in order to increase the dispersion in this region of shorter wave-lengths. An attempt is made to account for the observed phenomenon on the basis of multiple ionization. The atom absorbs energy sufficient to remove a K electron to the first permissible unoccupied orbit and also to eject an outer electron. One is led to the conclusion that probably similar fine structure might be obtained for all elements under suitable conditions.

6. The intensity of reflection of the $K\alpha$ line of carbon from a quartz surface. ELMER DERSHEM and MARCEL SCHEIN, *University of Chicago*.—The $K\alpha$ line of carbon ($\lambda=44.6\text{\AA}$) was reflected from a polished quartz surface and the intensity of the reflected radiation measured for glancing angles of incidence between $1^\circ 15'$ and 8° . The apparatus and methods have been previously described (Phys. Rev. 34, 1015 (1929)). The curve obtained by plotting the experimental values of reflected intensity against glancing angle of incidence is compared with various curves computed from the theoretical value of the index of refraction given by the Drude-Lorentz dispersion formula and values of the absorption coefficient obtained by the extension to this long wave-length region of various well-known empirical formulas relating to x-ray absorption. A calculated curve which is in good agreement with the experimental curve may be secured by the use of a mean of the values of the absorption coefficient for this wave-length in quartz which are given by the different empirical formulas.

7. An x-ray search for the origin of ferro-magnetism. J. C. STEARNS, *University of Denver*.—A sensitive null method, employing two crystals and two ionization chambers, was used to detect any change in the intensity of the Molybdenum $K\alpha$ reflected from a magnetic crystal when this crystal was magnetized. This method was capable of detecting from 1.0 to 0.1 percent change in the intensity, according to the intensity of the reflected beam. Crystals of magnetite and silicon were used. The change in the intensity of the x-ray beam was computed on the basis of the alteration of the structure factor due to the orientation of the electronic orbits by the magnetic field. The experimental results indicate that there is no change in the reflecting power of crystals of magnetite or silicon steel due to magnetization. It is concluded that electrons revolving in inner orbits within the atom cannot account for ferro-magnetism. On the basis of present atomic models and present experimental evidence it appears that the ultimate magnet should be identified with the spinning electron.

8. Magnetic properties of thin films of cobalt. E. P. T. TYNDALL and W. W. WERTZBAUGHER, *University of Iowa*.—The films are deposited electrolytically on brass tubes from a 3% solution of cobalt ammonium sulphate with the addition of boric acid. The magnetic properties are largely dependent on the amount of boric acid present in the solution. Films deposited from solutions nearly saturated with boric acid show almost complete magnetic saturation at $H=200$ gauss ($I_{\max}=1300$ c.g.s. units) and have very high remanence, about 98% of the maximum intensity of magnetization. The reciprocal of the coercive force is roughly proportional to the film thickness for films from 30 to 130 $m\mu$ thick, in approximate agreement with the relation previously found for iron (Phys. Rev. 30, 681 (1927)). Films from less acid solutions depart considerably from this relation. The properties of the films are undoubtedly partly due to occluded hydrogen, the effect of which is at present being investigated by heating the films.

9. Will the magnetic pole vanish? F. W. WARBURTON, *University of Oklahoma*.—By considering the parallel plate condenser and the long solenoid as sources of uniform electric

and magnetic fields respectively, the physical picture of the behavior of dielectrics and of magnetic media (in terms of displacement charge and of the equivalent magnetization current appearing at the respective surfaces) is very evident. The picture is simple and obviates the need of defining and using the fictitious magnetic unit pole even in elementary presentations. E , like B , is dependent on the medium, while D and H are the fields when dielectrics and magnetic media are absent. Non-uniform fields may be considered by the superposition of simpler cases. Were the charge on a condenser rather than the potential difference maintained constant a potential $V' = \int D ds$ would be useful as well as the ordinary potential $V = \int E ds$. Somewhat similarly a scalar magnetic potential $\phi' = \int H ds$, related to ampere-turns, is rather more useful than $\phi = \int B ds$, because it is the current in the solenoid and therefore H , not B , that is externally controlled. H and B can be derived from the corresponding vector potentials, A' and A .

10. Reflection of zinc atoms from NaCl crystals. HAROLD A. ZAHL, *University of Iowa*.—Zinc atoms issuing from a boiler at a temperature of 600°C are in part specularly reflected from a clean cleavage surface of a rock-salt crystal. Measurements, by means of a rotating sector disc-velocity-filter, of the velocity of the specularly reflected beam show that it contains atoms of but one velocity (or at least a very limited range of velocities). This velocity varies with the angle of incidence as shown below.

θ	vel(m/sec)			Average	$\phi \times 10^{14}$
22.5	763	736	761	753	4.4
45.0	666	672	683	674	12.1
67.5	712	689	695	699	22.2

An equation of the form $\lambda = h/mv = 2d(1 - 2\phi/mv^2 - \cos^2\theta)^{1/2}$ will not represent these results if ϕ is a constant. If it is assumed that ϕ varies with the angle of incidence then of course the equation may be made to fit. Values of ϕ calculated on this assumption are given in the table.

11. Specular reflection of atoms from crystals. A. ELLETT, *University of Iowa*.—The existence of specularly reflected nearly monochromatic beams of atoms and the behavior of these beams on reflection from two crystals in succession (Phys. Rev. **34**, 493, (1929)) is most readily understood as a wave or diffraction phenomenon. Neither the previous observations on cadmium nor those just reported on zinc can be represented by the equation $\lambda = h/mv = 2d(1 - 2\phi/mv^2 - \cos^2\theta)^{1/2}$ if ϕ is supposed to be constant. If it is assumed that ϕ varies with the angle of incidence and this equation used to calculate the appropriate values, we find

θ	22.5°	45°	67.5°
$\phi_m \times 10^{14}$	4.4	12.1	22.2
$\phi_{cd} \times 10^{14}$	4.84	13.2	19.6

The fact that the values obtained run roughly parallel may be significant. These values of ϕ correspond to the existence of a repulsive force acting upon the impinging atom and to values of the refractive index for phase waves $\mu = [1 - 2\phi/(mv^2)]^{1/2}$ less than unity. Both Davisson and Germer and Farnsworth have reported dispersion of the refractive index for electron waves, but the range of variation is much less than that found here.

12. Secondary electrons from contaminated metal surfaces. PAUL L. COPELAND, *University of Iowa*.—Small quantities of grease, or gases, or foreign metal upon a metallic surface have in the past been the cause of many spurious electrical effects. Stuhlmann and Compton cite a spurious contact potential difference of some 60 volts. Using electron reflection as a tool some of the properties of such surfaces have been investigated. The presence of surface impurities on a tungsten wire greatly increases reflection or secondary emission when electrons strike the filament. Surface fields are set up retarding the reflected electron; in some cases the film actually is an insulating layer which breaks down under a potential difference of some 50 volts, which may account for the results of Stuhlmann and Compton.

13. Electron energy losses in mercury vapor. CASTLE W. FOARD, *State University of Iowa*.—An improved magnetic spectrum method was used to determine the energy losses

sustained by slow speed electrons in mercury vapor. Electron energies up to 60 volts were used, the main region of interest being from 0 to 25 volts. The energy losses detected, below that required for ionization, were; 4.9, 5.4, 6.7, 7.7, 8.8, 9.8 volts. These correspond to practically all the transitions of a valence electron from the basic 1S level up to each of the higher levels to 4P. No evidence of other losses such as are observed by the photoelectric method was found. At voltages above 10.4, the ionization potential, electrons seem to be able to give up any quantity of energy in excess of that required for ionization, the higher losses being favored. A very interesting loss of 11.07 volts has been found, which has not been recorded heretofore. It begins to be resolved at about 18 volts, and grows steadily with increasing voltage in much the same manner as the 6.7 volts loss. It is thought that this loss involves the displacement of both valence electrons from their normal levels.

14. On the electric arc drawn in vacuum. RAGNAR TANBERG, *Westinghouse Elect. Mfg. Co.* (Introduced by J. Slepian).—In an electric arc drawn in vacuum, the cathode only contributes vapor to the maintenance of the arc, if the arc is of sufficiently short duration. The speed of the vapor emitted from the cathode spot is of the order of 15×10^5 cm/sec. and the temperature calculated from this molecular velocity is of the order of 500,000°K. Low voltage and high voltage vacuum arc forms have been observed, depending upon the location of the cathode spot relative to the anode. The low-voltage form appears when the cathode spot is so located as to discharge the cathode vapor into the arc stream. The highly ionized cathode vapor in this case prevents the development of negative space charges which otherwise would build up. The high voltage form appears when the path of the cathode vapor does not coincide with the arc stream. Motion of the arc in a transverse magnetic field between solid metal electrodes in a direction opposite to that which would be expected from ordinary electrodynamic considerations has been observed and explained by the bending of their path by the magnetic field and subsequent impingement on the cathode surface of some of the positive ions in the cathode vapor.

15. Voltage-intensity relations of the cadmium spectra. DEVER COLSON, *University of Iowa*.—The critical potentials for different spectrum lines are given by spectrum analysis. Qualitative observations of these critical potentials have been made by Ruark and Chenault and Esclanton and have been used for the differentiation of the different orders of the spark spectra of cadmium. The present work gives more exactly the critical potentials of the more prominent arc and spark lines and traces their behavior as a function of the energy of the impacting electron. The existence of 2^3D orbits suggested but not adopted by Von Salis is indicated.

16. Absorption of light by flames containing sodium. C. D. CHILD, *Colgate University*.—The intensity of sodium light from a series of flames into which a saturated solution of sodium chloride is sprayed was found to vary approximately as the square root of the number of flames. As the amount of sodium in the flames is diminished the ratio between the light from several flames and that from one becomes greater. These observations may be explained by assuming; first, that the number of sodium atoms in the flame which are able to emit light in a given direction or to absorb light going in that direction is very much less than the total number of sodium atoms in the flame and secondly that even this limited number is greatly diminished by the process of absorbing sodium light which is going in the direction considered. A possible explanation for these assumptions is that atoms emit light in a direction which bears a definite relation to the orientation of the atom at the time it is emitting the light and absorbs only light which is going in the same direction.

17. The use of homogeneous coordinates in physics and chemistry. HERBERT J. BRENNEN, *Northwestern University*.—It is shown that homogeneous coordinates can be advantageously used in the following cases: 1. A generalisation of the third law of thermodynamics. 2. Equations of state. 3. A generalisation of the phase rule to take account of the change of vapor pressure of a substance, at constant temperature, with the size of the particle. In order to take account of the change of vapor pressure of a substance at constant temperature with the

total pressure on the system, the phase rule may be still further generalised by the introduction of a new coordinate the total pressure on the system. 4. The restricted theory of relativity where the four planes are: $X=0$, $Y=0$, $Z=0$ and $\mathcal{G}=0$, where \mathcal{G} is the product of the velocity of light and the time. 5. The general theory of relativity where we have four surfaces analogous to the four planes in the restricted theory. Hence, by the use of homogeneous coordinates, four dimensional relativity becomes a problem in a space of three dimensions.

18. Zodiacal light and magnetic storms. E. O. HULBURT, *Naval Research Laboratory*.—From April, 1853, to April, 1855, Rev. George Jones, U. S. N., observed the zodiacal light every night, weather and other things permitting. A comparison of his record with the Greenwich magnetic storm list gave the following results: In this period there were 26 magnetic storms, or storm groups, and 23 periods of abnormal zodiacal light, 16 of which followed within 3 days after a magnetic storm. 10 storms occurred on dates for which there were no zodiacal light observations, and there were 7 cases of abnormal zodiacal light with no accompanying magnetic storms listed. The abnormalities in the light were mainly fluctuations, and sometimes an unusual brilliance or distribution in the heavens. The correspondence between zodiacal light behavior and magnetic disturbance indicates, but does not prove, that the light comes from particles originating from the terrestrial atmosphere, in accord with the views of Barnard and others. It seems possible to sketch out a qualitative theory by considering the behavior of the high flying terrestrial ions under the influence of gravitation, light pressure and the terrestrial magnetic field.

19. Changes in the ozone concentration of the atmosphere. RICHARD RUEDY, *Toronto*.—An ozone layer equivalent to 3 mm being situated in the atmosphere above altitude 40 km, that is being contained in a column equivalent to not more than 100 m of air at sea-level, corresponds to a volume percentage of 10^{-3} to 10^{-4} , a value agreeing roughly with that calculated from Nernst's theorem for thermal equilibrium at 6000° . At concentrations of this order, the natural thermal decomposition of O_3 cannot be neglected as has been proposed, when explaining the decrease of O_3 towards the equator. It becomes also apparent in cyclonic, or anti-cyclonic, conditions, owing to the heat radiated to, or from, the troposphere. During the "ultra-violet outburst's" of the sun, as proposed for explaining auroras and magnetic storms, the ozone-building radiations could reach 6 times, the destructive radiations but 1.2 times their stationary values. The daily measurements recently made at Arosa, Marseille, Oxford, etc. do not exhibit an increase in O_3 for the few days preceding or following the strongest magnetic storms. (October 15, 1926, July 7/8, and October 18, 1928). If the outburst lasted only for one-half hour, the increase would have been smaller than the error of observation (0.01 cm); on the other hand, increases by 0.04 cm are observed in the absence of magnetic storms.

20. Electrodynamical damping in pulsating stars. ROSS GUNN, *Naval Research Laboratory, Washington, D. C.*—Small radial pulsations of stars are shown to be highly damped by electrodynamic forces when the star has a magnetic field. The author's theory of the permanent magnetic field of the sun indicates that the field is produced by regenerative means which is triggered off by a small initial field. The small initial field probably arises from the rotation of the star combined with a separation of charge, although it may conceivably arise in other ways. Thus rotating stars will have a magnetic field and cannot pulsate, and conversely stars which pulsate have no magnetic field and do not rotate. Cepheid variables are observed to pulsate and therefore have no magnetic field and do not rotate. This is in keeping with the idea that Cepheid variables, being youthful giants, are so large that they would be unstable under rotation. These considerations appear to remove the difficulties encountered by Eddington in his detailed theory of star pulsations.

21. The analysis of cosmic-ray observations. LE ROY D. WELD, *Coe College*.—Millikan and Cameron find evidence of several distinct absorption coefficients for the cosmic rays in deep lakes, suggesting a spectrum of definite wave-lengths. In this paper, a general method of least-square adjustment of non-linear observation equations is adapted to the analysis of the cosmic-ray absorption curve, in order to determine the most probable values of the two constants for each component of the radiation.

22. Mass-weight ratio of metals under strain. P. I. WOLD, *Union College*.—The late Dr. Charles F. Brush conducted work for years on the mass-weight ratio of metals. One of his methods of experimentation consisted in weighing certain alloys while they were subjected to very considerable pressure. He found losses in weight amounting to as much as one part in 40,000. Measurements have been carried on for the last two years on alloy specimens, which he had prepared, to see if independent observers could reproduce his results. On such specimens changes amounting to about one part in 150,000 were obtained. The curves of weight against pressure show the same characteristics as obtained by Dr. Brush. While the changes are small, they are substantially larger than can be ascribed to the errors of the balance or to temperature changes.

23. The surface tension of molten glass at temperatures near the melting point. W. B. PIETENPOL AND H. H. SCOTT, *University of Colorado*.—A new method has been devised by which the surface tensions of a number of glasses of different composition have been determined throughout a range of temperature of approximately 200°C. just above the softening points. The method is termed "The Bulb Method" and is similar to the soap bubble experiment in which the excess of pressure within the bubble can be balanced against a small head of liquid in a manometer. It was found that the weight of the glass bulb needed to be considered and a formula is developed giving the relation between surface tension and pressure in which the correction factor is introduced. Throughout the range to which the method is applicable, it is found that the surface tension of glass varies but slightly with temperature. The magnitude of the surface tension for different glasses is of the order of 250 to 350 dynes per cm.

24. Thermal expansion of lead. PETER HIDNERT AND W. T. SWEENEY, *Bureau of Standards*.—Data by Hidnert and Sweeney on the linear thermal expansion of one sample of cast lead and various lead-antimony alloys between 20 and 60°C were published in 1924 by Vinal, "Storage Batteries." Since then additional determinations were made on three samples of cast lead over various temperature ranges between 20 and 300°C. The following results were obtained:

Sample ¹	Lead content Percent	Average coefficients of linear expansion per Degree Centigrade				Difference in length before and after Expansion test Percent
		20 to 60°C. $\times 10^{-6}$	20 to 100°C. $\times 10^{-6}$	20 to 200°C. $\times 10^{-6}$	20 to 300°C. $\times 10^{-6}$	
1215 ²	99.8	{ 29.0	28.9	29.7	30.9	−0.01
		—	28.8	29.4	31.0	.00
1144	99.9	28.3	28.6	29.5	31.2	.00
1001 ³	—	29.2	29.6	31.2	32.5	+ .02

¹ Samples 1215 and 1144 were cast in sand molds, and sample 1001 in a pre-heated steel mold.

² Values given on second horizontal line were obtained on a second test.

³ Sample 1001 cast from same ingot as sample 1215.

The differences obtained in the coefficients of expansion are evidently due to variations in the methods of casting.

25. Two different types of association of alcohol molecules in the liquid state. G. W. STEWART, *University of Iowa*.—By x-ray diffraction studies of liquid alcohols, including twenty-one octyl alcohols, eleven primary n-alcohols, and nine additional isomers of primary normal alcohols, evidence is obtained of two types of association of molecules. When the OH group is attached to the terminal carbon atom or the one adjacent thereto, the molecules are associated primarily in pairs with the OH group adjoining and the median lines of two chains in the same line. At the same time there is a more or less orderly lateral arrangement of these pairs of OH groups. When the OH group is attached to any other carbon atom in the chain, then the double molecules disappear and the association is side by side. There is no exception to these conclusions in the liquids studied.

26. On the theory of the solar corona. E. O. HULBURT, *Naval Research Laboratory*.—The outer atmosphere of the sun is assumed to be composed mainly of charged particles, which are actuated by gravitation, radiation pressure and the magnetic field of the sun. By distillation along the lines of magnetic force the particles collect in the lower latitudes of the solar outer atmosphere and by their diamagnetism and drift currents reduce the magnetic field approximately to zero in this region, leaving a stray field at the poles. Thus the coronal streamers, prominent during sun-spot minima, are regarded as owing their form to the magnetic field of the sun. Whereas the wide-spreading structureless coronal luminosity expending out from the lower latitudes is due to an accumulation of ionization which reduces the magnetic field to a low value and permits the radiation to blow the particles out to great distances. During maximum solar activity there is sufficient ionization of the outer atmosphere to reduce the magnetic field to a low value even at the poles, and hence the outer atmospheric spray extends roughly equally in all directions, in accord with the appearance of the corona.

27. Resistance of an electrolytic conductor at various frequencies. D. E. RICHARDSON, *University of Chicago*. (Introduced by J. Barton Hoag.)—The resistance of a conductor, as defined by the ratio of electrical energy converted into heat and the square of the current, is a function of the frequency of the current because of the non-uniform current density throughout the cross-section of the conductor. Classical electrical theory offers an equation for this skin effect. This has been verified for metallic conductors for frequencies up to one megacycle. Using a calorimetric method, the equation is now verified in a particular case of electrolytic conduction (30% solution of H_2SO_4) for frequencies up to eight megacycles (37 m). It is concluded that the resistivity of this electrolytic conductor is independent of the frequency up to eight megacycles, since this assumption was made in the derivation of the equation. Measurements of the currents were made by comparing photometrically the intensities of two filaments, one carrying the high frequency currents, the other direct current.

28. Change of spacing of positive column striations with temperature. F. M. SPARKS AND CHAS. T. KNIPP, *University of Illinois*. Cassen (Phil. Mag. 268, 948 (1926)) predicts that the separation of the striations in the positive column of a discharge tube should increase almost linearly with the absolute temperature. A discharge tube was heated in a liquid bath, the temperature range being from room temperature to 165°C . Hydrogen was used in the tube, but only the blue striations, due to impure hydrogen (Handbuch der Physik, vol. 14, p. 298) were obtained. To detect any temperature lag or any change in the characteristics of the gas the separations were noted with both increasing and decreasing temperature. The resulting curves showed no appreciable lag. Cassen's prediction is verified for the wide striations, at pressures around 1 mm Hg, but for the narrow striations, above 1.5 mm, the separation decreases with increasing temperature. However, the separation, in general, reaches a minimum value, and then begins to increase with increasing temperature. A series of temperature-separation curves were plotted for hydrogen at 2.5 mm, using three different values of current, after successive additions of impurity. The general shape of the curves remained the same, but were shifted to smaller values of separation, reaching a minimum, and then were shifted back to greater values.

29. A glass window mounting for withstanding pressures of 30,000 atmospheres. THOS. C. POULTER, *Iowa Wesleyan College*. The range in the field of optical study at high pressures has been extended from approximately 4,000 atmospheres to 30,000 atmospheres or even higher by the development of a window mounting that will withstand these higher pressures. This window mounting consists of a piece of glass 12 mm in diameter and 8 mm in thickness and having one of its flat surfaces placed over a 6 mm hole in a polished surface of hardened "high speed" steel disk. No gasket material is used between the steel and the glass. Since the flowing of the gasket material under pressure was the main source of unequal strains in the windows causing them to break, the piece of "high speed" steel is held in place by means of a large screw which in turn carries another window similarly mounted so as to catch flying materials in case the first window shatters.

30. Magnetostriction measurements using a heterodyne beat method. A. B. BRYAN AND C. W. HEAPS, *The Rice Institute*. Two circuits oscillating with radio frequency produce a beat note which is itself made to beat slowly with a tuning fork. A photographic record of this slow beat is obtained on a moving photographic film. A parallel plate condenser in one of the oscillating circuits has its capacity changed by the magnetostriction of a nickel wire supporting one of the plates. From the photographic record the magnetostriction can be accurately determined. A search coil around the nickel wire picks up Barkhausen discontinuities which are then amplified and recorded on the film simultaneously with the magnetostriction effect and a time scale. Indications are that a Barkhausen discontinuity is accompanied by a sudden change in the length of the nickel wire. The apparatus detects a length change of about 10^{-7} cm in the length of the wire and can be used for a very rapid cycle of magnetization. Magnetostrictive hysteresis is to be investigated in different materials.

31. Diffraction of molecules. OTTO STERN, *Hamburg University*. (Introduced by W. L. Severinghaus.)

32. Deflection of hydrogen positive rays by calcite. A. J. DEMPSTER, *University of Chicago*. A series of photographs of the reflection patterns of hydrogen canal rays from a calcite crystal has been obtained with different angles of incidence showing a gradual alteration in the pattern with angle. Patterns have been obtained from three different calcite crystals. A charging up of the surface was observed in one case, as shown by the deflection of the negative ions in the canal ray beam. The amount of the deflection is of the order of magnitude required by the first of the Laue equations, $a(\alpha - \alpha_0) = \lambda$, if $\lambda = 0.0017\text{\AA}$, as given by the de Broglie formula. The lines in the patterns in many cases form arcs of circles passing through the center. This suggests the reflection of the rays at the planes belonging to various zones as found with x-rays in Laue spot photographs. The angles at which reflection occurs when small are influenced very greatly by any surface energy or change of refractive index, even if very small. Radiation is excited in the calcite by the impact of the canal rays, which issues outside of a critical angle of approximately 0.01 radian with the surface. The refractive index deduced agrees with that of radiation of the wave-length of the $K\alpha$ calcium line.

SODIUM AND MAGNESIUM SPARK LINES IN THE FAR ULTRA-VIOLET, AND THE QUANTITATIVE APPLICA- TION OF THE IRREGULAR DOUBLET LAW TO ISOELECTRONIC SEQUENCES

BY J. E. MACK¹ AND R. A. SAWYER
UNIVERSITY OF MINNESOTA AND UNIVERSITY OF MICHIGAN

(Received January 13, 1930)

ABSTRACT

New levels in Na III, Mg IV, and Mg V are identified through the transition $2s \leftarrow 2p$. The value of the negative term $2s2p^5\ ^3P$ of O I is predicted.

The relativistic screening number $\sigma_2(L_{21}L_{22})$, is 3.19 for $Z=10, 11$ compared with the value 3.49 for heavier atoms, usually considered independent of Z . The difference is probably due to outer screening.

Wentzel's result $\sigma_1(n, l+1) - \sigma_1(n, l) = 0.58 \cdot 2'n$ for the first order screening number σ_1 in x-rays is applied instead of the usual qualitative form of the irregular doublet law to determine the rate of dependence of the transition energy $2s^22p^5 \leftarrow 2s2p^6$ upon Z in the fluorine-like isoelectronic sequence. The extremely high result, $49 \cdot 10^3 \text{cm}^{-1}$, is verified by the new Na III and Mg IV data. Certain regularities in the curves showing the rates of dependence of the irregular doublet transition frequencies upon the atomic number in isoelectronic sequences, as functions of the number of electrons present, may be used for interpolation of these rates.

SEVERAL new lines and some old ones, due to the transition $2s \leftarrow 2p$ in the spark spectra of sodium and magnesium, have been photographed with the University of Michigan's one meter vacuum spectrograph and classified.²

Due to the necessity of breaking down the rare gas shell $2p^6$, the several times ionized atoms in this part of the periodic table require more energy for excitation than any others of the same stage of ionization except those isoelectronic with helium and hydrogen. Attempts to obtain the lines of Na IV and Al IV and extend the scheme of Mg III have been thus far unsuccessful. The failure to obtain the PP^o group of Na IV expected at $244 \cdot 10^3 \text{cm}^{-1}$, in the face of the success with Mg V, may be attributed to the inconvenient physical properties of sodium. We had to insert the sodium as a

¹ National Research Fellow.

² We are indebted to Messrs. R. F. Bacher and G. R. Miller for aid in the photographic work.

TABLE I. Lines and new levels in sodium and magnesium.

SODIUM					
Lines			New Levels ($\cdot 10 \text{ cm}^{-1}$)		
(Bowen)	Int λ	Int λ ν ($\cdot 10 \text{ cm}^{-1}$)	Assignment	Na III	
2 372.04	3	372.16	$2s^2 2p^6 \text{ } ^1S_0 - 2s^2 p^5 3s \text{ } ^1P_1^{\circ}$		0
1 376.34	2	376.63	$1S_0 - \text{ } ^3P_1^{\circ}$		138
	1	378.34	$2s^2 2p^5 \text{ } ^2P_{1/2}^{\circ} - 2s^2 p^6 \text{ } ^2S_{1/2}$		26431
	1	380.33	$2P_{1/2}^{\circ} - \text{ } ^2S_{1/2}$

core in a hollow aluminum electrode, whereas whole electrodes were easily made of magnesium.

Table I shows all the lines, $\lambda < 380$ of Na, and $\lambda < 360$ of Mg, that have ever been detected. The already classified Na II and Mg III lines are included for completeness.³ The present assignment of Mg $\lambda\lambda 320, 323$ has been suggested among other possibilities by Turner.⁴ Now the quantitative applicability of the irregular doublet law (Part III, below), and the relative unlikelihood of the strong occurrence of such x-ray transitions as $s^2p^5s^2 \leftarrow sp^6s^2$ in magnesium alone, make this assignment certain. The intensity relations, especially when examined in connection with those given in Millikan and Bowen's first paper on far ultra-violet spectra, (Table I, Mg, first column) are most satisfactory.

Table II gives the relativistic screening numbers $\sigma_2(2s^22p^4$ or $2s2p^5)$ for oxygen-like systems and $\sigma_2(2s^22p^5)$ for fluorine-like systems, respectively, as functions of the atomic number Z . The number σ_2 is calculated from the Sommerfeld formula $\Delta\nu = \alpha^2 R(Z - \sigma_2)^4 / n^3 l(l+1)$, which applies in these cases if $\Delta\nu$ is the doublet separation or the overall separation of the triplet.⁵ The frequency of the transition $2s \leftarrow 2p$, is given in the next to last column, while the last column shows the differences in the frequency of the transitions $2s \leftarrow 2p$ for successive members of each isoelectronic sequence. The extraordinarily high values of these differences will be discussed below (Part III). The numbers in parentheses are interpolated. Backward extrapolation of the next to last column to the arc spectra shows that O I $sp^5\ ^3P$ lies about $15 \cdot 10^3 \text{ cm}^{-1}$ above the lowest state $s^2p^3\ ^4S$ of O II, and F I $sp^6\ ^2S$ about $16 \cdot 10^3 \text{ cm}^{-1}$ above the lowest state $s^2p^4\ ^3P$ of F II. Neither of these negative levels has been observed.

The mean error in wave-length separations is about 0.03A, which at 300A amounts to 30 cm^{-1} . Thus the screening numbers at the bottom of each sequence in Table II are uncertain by about 0.03, while those at the top are perhaps ten times as accurate. Only in F II is it possible to distinguish, with the available measurements, between the values of the s^2p^4 and the sp^5 screening.

³ Detailed references to sources of spectroscopic data are omitted. The x-ray references may be found in Handbuch der Physik 21, 338; optical spectra, in the forthcoming University of Michigan term tables. Of special importance for this paper are the following:

II. ON THE REGULAR DOUBLET LAW

Fig. 1 shows the screening numbers from Table II, with the other relativistic $2p$ -screening numbers, calculated with the aid of the Goudsmit separation factors.⁵ The assumption of normal coupling, where necessary for calculating the screening, is well justified.⁶ The fourth power formula is applied throughout, for it is a good approximation to call the $2p$ -electrons non-penetrating. All principal quantum numbers omitted in the notation are 2. The $1s^2$ shell is present in each configuration. Within the limits of experimental error, all the values decrease smoothly toward horizontal asymptotes.⁷ The p^2 and sp^2 curves are considerably flatter than their neighbors.

The addition of an s -electron to s^2p^5 makes a change only on the order of 0.01 in the $2p$ -screening, quite in contrast with the case where less than five $2p$ -electrons are present, as in N I, for instance, where the presence of a $3s$ -electron alters the screening by half a unit. This often-noted constancy

of the many closed shells, are probably sufficient to account for the discrepancy.⁹

III. ON THE IRREGULAR DOUBLET LAW

Heretofore the irregular doublet law has been applied to optical spectra only in the following qualitative rule: In an isoelectronic sequence, the transition frequency $\nu(n, l) - \nu(n, l+1)$ is approximately a linear function of the atomic number Z .

The irregular doublet law for x-rays can be stated, following Wentzel, in a refined form¹⁰ as

$$\sigma_1(n, l+1) - \sigma_1(n, l) = 0.58 \cdot 2^l n \quad (1)$$

for inner electrons; where n and l have their usual spectroscopic meaning, R is Rydberg's energy constant, and $\sigma_1 = Z - n (\nu_{\text{red}}/R)^{1/2}$. If $5 \cdot 10^{-5}(Z - \sigma_2)^4$ may be neglected compared with ν/R , as it may be for our purposes among the light elements with which we are concerned,¹¹ then ν_{red} is the same as ν , the energy required to remove the electron.

From Eq. (1) and the definition of σ_1 , we have

$$\nu_{\text{red}}(n, l) - \nu_{\text{red}}(n, l+1) = 0.58 \cdot 2^l R [0.58 \cdot 2^l + 2(Z - \sigma_1(n, l+1))/n] \quad (2)$$

$$\frac{\Delta}{\Delta Z} [\nu_{\text{red}}(n, l) - \nu_{\text{red}}(n, l+1)] = \frac{0.58 \cdot 2^{l+1} R}{n} \left[1 - \frac{\Delta}{\Delta Z} \sigma_1(n, l+1) \right] \quad (3)$$

for inner electrons.

With the aid of the newly found data we can study (Table III and Fig. 2) the frequency of the irregular doublet transition $2s \leftarrow 2p$ as a function of the atomic number (Z) and the net charge (indicated by a roman numeral), for systems of one to nine electrons. The rows labeled "upper config." and "lower config." in Table III show the electron configurations between which the transition takes place. All omitted principal quantum numbers are 2. The $1s^2$ shell is present except in the configurations marked () or (1s). The row $(Z+1) \text{ II}$ gives the transition frequency¹² (in terms of the Rydberg constant) for the first spark spectrum isoelectronic with the arc spectrum of atomic number Z . The row $(Z+1) \text{ II} - Z \text{ II}$ (row A) gives the rate at which the transition frequency for first spark spectra depends upon Z , while the row $(Z+1) \text{ II} - Z \text{ I}$ (row B) gives the rate at which the transition frequency depends upon Z in each isoelectronic sequence. The organization

⁹ The importance of such disturbances is shown, for instance, by the fact that the separations for some of the one-electron doublets among the heavier atoms actually have negative values. The case of Hg II $5f^2 F \Delta \nu = -257$ (F. Paschen, Preus, Akad. Sitzungsber. p. 536 (1928)) is especially striking.

¹⁰ G. Wentzel, Zeits. f. Physik 16, 41 (1926); A. Sommerfeld, "Atombau" 4th ed. p. 459.

¹¹ At $Z=10$, Ne II, "reduction" decreases the $-2s$ term (L_{11}) from $3.563R$ to $3.509R$, and the $-2p$ term (L_{21}) from $1.592R$ to $1.585R$.

¹² In the optical part, the frequency given is the difference between the lowest level in the lower configuration and the lowest level of the same multiplicity in the upper configuration.

										mean 0.23	mean 0.16	mean 0.14

^a (Z+2)III - (Z+1)II is used here because the configurations sp^5 , sp^6 are unknown in the arc spectra.

of Table III will be made clear by a comparison of columns 8 and 9 with the last two columns of Table II (e.g. $216270 \text{ cm}^{-1} = 1.971R$, and $48040 \text{ cm}^{-1} = 0.44R$). Table III is divided by vertical lines into an optical part (left) and an x-ray part (right); column 9 must be included in both parts because of the double role of the L levels of Ne II. Elements 42 Mo, 74 W, and 92 U are chosen as samples for the x-ray part.

No modification of the meaning of any quantity is needed in putting the x-ray data in row $(Z+1)II$. But for clearness the "reduced" values are used in the rest of the x-ray part of the table, which means simply that the complicating effects of the relativity and spin corrections are eliminated.

There are no direct data on isoelectronic sequences of x-ray spectra, such as would be required to fill the spaces ditto-marked in the table. But all the difference between the quantity that belongs in such a space, and the quantity recorded just above it, is due to the influence of an outer electron. The presence of such an electron can have but little influence on an x-ray energy level, and clearly the subtraction of one L -level from another to determine the transition frequency, would tend to cancel out this little influence. So we can confidently conclude that the numbers in the spaces marked with ditto marks in row B should be very nearly the same as those above them in row A .

The ordinary $L_{21}L_{22}$ first order x-ray screening number, and its rate of dependence on Z (e.g. $(14.8 - 7.48)/(41 - 9) = 0.23$) are given in the last two rows.

We shall now show that the values of the numbers in italic type, column 9, are in quite close agreement with values that may be calculated for them simply by the use of the x-ray data to the right of the lines in Table III, the irregular doublet law, and the ionizing potential¹³ of Ne I.

The quantities appearing in the row $(Z+1)II$ reduced and row A of Table III are simply the $\nu_{\text{red}}(2, 0) - \nu_{\text{red}}(2, 1)$ in Eq. (2) and its derivative in Eq. (3), respectively. So as long as we confine ourselves to inner electrons (i.e. to x-ray levels) the quantities in row A are given by Eq. (3). And so are the quantities in row B , from our discussion of the ditto marks. Thus, using the average slope of σ_1 from the last row of the table, we have directly from Eq. (3):

$$\begin{aligned} (\text{italic numbers, Table III}) &= 0.58R (1 - 0.23) \\ &= 0.45R \\ &= 49 \cdot 10^3 \text{ cm}^{-1} \end{aligned}$$

an extraordinarily high value for the rate of dependence of an irregular doublet transition upon Z in an isoelectronic sequence, but in good agreement with the experimental data.

Fig. 2 shows the rate of dependence of the transition frequency $2s \leftarrow 2p$ upon the number of electrons present, for the cases we have been considering: Table III, row A , (first spark spectra)¹⁴ and row B (isoelectronic sequences)

¹³ Or any other data that gives the σ_1 's of Ne.

¹⁴ The abscissae for this curve are shifted by half a unit, since it is a first difference curve.

The change in scale factor masks the fact that the curve for the x-ray part of the figure, is almost horizontal. Three facts readable from Fig. 2 are worth pointing out here:

1). The extrapolability of the x-ray curve to $0.45R$ for the fluorine-like sequence, which has been discussed above.

2). The uselessness of attempts to apply Wentzel's regularity to outer electrons.¹⁵

3). The smoothness of the isoelectronic sequences curve, compared with the successive first spark spectra curve, from $Z=1$ to $Z=9$. Wide irregularities occur in the optical part of row *A* curve, superimposed upon the general upward trend with increasing Z that might be expected due to the increasing differences in screening between $2s$ and $2p$, as the K and L shells are being added. It is often pointed out that such irregularities can be explained

Fig. 2. Rates of dependence of the transition frequency $2s \leftarrow 2p$ upon the atomic number, in successive first spark spectra (*A*) and in isoelectronic sequences (*B*).

qualitatively by considerations based on the discrete changes in the number of electrons present: such as the formation of stable configurations at 2 and 4 and the neglect of higher multiplicities at 4, 5, and 6. To the first degree of approximation these irregularities are absent in the row *B* curve, because the differences in an isoelectronic sequence involve identical electron structures. Quite generally it appears that isoelectronic sequence irregular doublet transition curves such as the row *B* curve, depart from linearity only by a slight upward curvature, with a peak wherever the lower configuration is a Pauli shell.¹⁶ (See the $4s \leftarrow 4p$ data, below).

The irregular doublet we have been considering ($2s$, $2p$) is uniquely favored for the quantitative application of the law to isoelectronic sequences,

¹⁵ E.g., B. C. Mukherjee and B. B. Ray, *Zeits. f. Physik* **57**, 345 (1929).

¹⁶ If we used $sp \leftarrow p^2$ in the beryllium-like sequence (the isolated point at 4, $0.22R$ in Fig. 2) we would eliminate the peak at 4. (Such a choice would also make the row *A* curve smoother, lowering the ordinate at 3.5 and raising that at 4.5 by $0.11R$). Similarly in the $4s \leftarrow 4p$ list below, the choice of $3d4s \leftarrow 3d4p$ instead of $4s^2 \leftarrow 4s4p$ would lower the ordinate for the 20-electron sequence to 0.110 .

for only here is it possible to excite an electron from a normally closed shell (here $2s^2$) in increasingly heavy atoms even up to those wherein the next shell with the same principal quantum number (here $2p^6$) is normally closed. But we can apply the regularities we have found for $2s \leftarrow 2p$, somewhat more crudely in other sequences. For instance, the following shows (in part) the rate of dependence upon Z in isoelectronic sequences, of the frequency $4s \leftarrow 4p$, analogous to Table III, row B :

lower config.													
No. electrons	1	• • • 11	12	13	• • • 18	19	20	21	• • • 27	28	29	30	
rate	0	.059	.069	.074	.089	.111	.185 ¹⁶	.116	.133	.147	.161	.219	

At 30 the experimental data stops, the $4s^2$ shell being so stable that there is no data on optical transitions involving $4s$ electrons for $Z > 30$; whereas the $4p$ electrons do not become inner electrons until $Z = 36$. It is not possible to calculate the rate in the sequence joining x-ray and "semi-optical" spectra (the bromine-like sequence in the case $4s \leftarrow 4p$) from Eq. (3) with the same accuracy as in the $2s \leftarrow 2p$ case, for the curvature and uncertainty in the x-ray, σ_1 curves increases with increasing principal quantum number.¹⁷ The rate for $4s \leftarrow 4p$ in the bromine-like sequence from Eq. (3) is about $0.58 \cdot 2(1 - .4)/4 = .17$.

Interpolations in such tables as this, allowing for the peaked but otherwise smooth character of the curves, should be quite reliable.

NEW MEASUREMENTS IN THE FOURTH POSITIVE
CO BANDS

BY ROGER S. ESTEY

WASHINGTON SQUARE COLLEGE, NEW YORK UNIVERSITY

(Received October 28, 1929)

ABSTRACT

That part of the fourth positive system of CO lying between 1970A and 2800A has been remeasured together with sixteen bands not previously observed. An equation for the band heads is given, the constants of which yield the values $D' = 12.00$ volts, $D'' = 11.17$ volts for the heat of dissociation.

Modifications in values of frequency have been small, while those of intensity have been rather large. Some discrepancies have been removed. Revision of intensity estimates permits a far more accurate comparison than previously with Condon's theory of intensity distribution and shows the superiority of Morse's $U(r)$ function. Using this function, the distribution of intensity among the bands of the fourth positive system agrees perfectly with Snow and Rideal's value of the moment of inertia for the normal state, $I_0'' = 15.0 \times 10^{-40}$ g cm².

The quantum assignment of Asundi's infra-red electronic bands has been revised.

INTRODUCTION

THE fourth positive band system of CO, which extends at least from 2800A to 1300A, has never been completely measured by any one investigator. The work on this system prior to 1926 is fully described by Birge.¹ His paper analyzes data taken by Deslandres (42 bands), Bair (22 bands), Duncan (14 bands), Lyman (100 bands), and Leifson (12 bands), all under low dispersion. Subsequent to 1926 papers have appeared on the energy levels of CO,^{2,3} the mode of dissociation,⁴ CO in active nitrogen,⁵ the isotope effect,⁶ and a series of papers on the structure of the various systems.^{7,8,9,10}

The initial vibrational levels of this system are the same as the final levels of the Angstrom bands and of the new bands analyzed by Herzberg,⁷ and Johnson and Asundi,⁸ while the final levels are the same as those of the Cameron bands and several absorption systems. These relationships are shown in Fig. 1, which diagrams the electronic energy levels for neutral CO. In addition to the bands just mentioned there are shown the third

positive and the three *A* systems. Asundi⁹ has contributed two other new systems, the five *B* and an unnamed system in the near infra-red. The absorption and emission systems described by Hopfield and Birge are also shown.

Fig. 1. Energy level diagram for neutral CO.

Asundi's vibrational analysis¹¹ of the infra-red system requires revision with respect to the initial state. The upper electronic level is at 57763 cm⁻¹ (Birge, private communication) rather than at 58927, and the most recent value¹² for ω_0' is 1173 cm⁻¹. This yields the equation for the infra-red bands

$$\nu = 9325 + (1173n' - 9n'^2) - (1726.5n'' - 14.4n''^2).$$

Accordingly the initial quantum numbering must be increased by one unit and the band called 1, 0 by Asundi is really the 2, 0 band.

The present knowledge of the fourth positive band system is somewhat inaccurate because it has been measured under low dispersion only, and because of a lack of satisfactory wave-length standards in the region which it occupies. Therefore it seemed advisable to remeasure as many bands as could be reached with a quartz spectrograph.

EXPERIMENTAL DETAILS

The CO bands were excited at 0.3 mm pressure in a water-cooled U-shaped discharge tube, the straight portion of which was viewed end on. This straight portion was 23 cm long and 6 mm in diameter. Large iron

¹¹ His equation is $\nu = 10489 + (1155n' - 9n'^2) - (1726.5n'' - 14.4n''^2)$.

¹² Mulliken, Phys. Rev. 32, 186 (1928).

electrodes permitted an input of 1.2 amperes at 2200 volts from a 3 KVA power transformer. Magnesium carbonate in an electrically heated side tube served as a source of CO_2 which later broke down to CO in the discharge. The vapor pressure of CO_2 over magnesium carbonate is constant at constant temperature. In this way fresh gas was provided as rapidly as required by the clean-up of the electrodes.

The pictures were taken on Hilger Schumann plates, or oiled Eastman 40's with a Hilger E 1 quartz spectrograph. This instrument has a dispersion of 3.91Å/mm at 2800Å and 1.21Å/mm at 1970Å, the limits of the range covered in this investigation.

Copper arc and spark lines and nickel spark lines as listed by Shenstone^{13,14,15} served as standards below 2500Å, while in the region above this iron standards as listed in volume VII of Kayser and Konen, "Handbuch der Spektroskopie," were used. The transformations between wave-lengths and wave-numbers were made with the aid of Kayser's "Tabelle der Schwingungszahlen."

RESULTS

The new measurements on the band heads are shown in the following table.

The assignment of vibrational quantum numbers (n' , n'') is substantially that given by Birge. A few bands given by him were not measured because of overlapping by other bands. Otherwise, all bands given by Birge, as well as many new bands, have been measured and quantum numbers assigned.

The new measures on fifty-eight bands yield the equation¹⁶

$$\nu = 64729.60 + (1497.63 n' - 17.262 n'^2) - (2149.08 n'' - 12.761 n''^2).$$

The column headed "O-C" in Table I lists the observed minus calculated values of the band heads as calculated from this equation. Unfortunately it was possible to measure bands of relatively large quantum numbers only. For this reason the equation written above probably does not express the origin of the system and the bands near it as well as the former equation¹⁶ does, although for the region represented by the bands of Table I the new equation is probably the better.

The plates showed clearly the presence of a single P , Q , and R branch in each band. The bands degrade to the red. Although they were unresolved at the origin and it was impossible to determine how many lines were missing, there is no reason to doubt the correctness of the assumption that these bands result from a $^1\Pi$ to $^1\Sigma$ transition.

DISCUSSION

Accuracy in our present methods of evaluating the heat of dissociation of a molecule from data on vibrational energy levels depends on our ability to extrapolate to $\omega_n = 0$ the $\omega_n:n$ curve. Fortunately in many cases including this one the $\omega_n:n$ curve is nearly linear over the known range, which facilitates extrapolation. The data in this paper, being more accurate and extensive, yield a more reliable extrapolation and provide a more certain value of the heat of dissociation than that previously reported.¹⁷ The heat of dissociation of a CO molecule in the normal state, as now determined, is 11.17 volts. To raise a CO molecule to the $^1\Pi$ level and dissociate it there requires 12.00 volts.

The large extent of the fourth positive system affords both opportunity and difficulty in discussing vibrational intensity relations. Table I gives, under the heading " I ", simple visual estimates of intensity, allowing as well as possible for overlapping bands and for large variations in plate sensitivity over the range considered. Fig. 2 shows in a graphical manner the intensities of the observed bands. The diameters of the circles are proportional to the intensities of the corresponding bands.

A theory has been given by Condon¹⁸ which predicts, from a knowledge of certain band constants including the moment of inertia, which bands of a system will be the most intense. A $U(r)$ curve (potential energy as a function of r) is drawn for each of the two electronic states involved. Such a curve

¹⁶ The next most recent equation (I.C.T. Vol. 5, p. 412) is $\nu = 64765 + (1499.0n' - 17.24n'^2) - (2154.7n'' - 12.70n''^2)$. $D = 11.2$ volts.

¹⁷ Birge and Sponer, Phys. Rev. **28**, 259 (1926).

¹⁸ Condon, Phys. Rev. **28**, 1182 (1926).

shows the extremes between which a molecule with a given amount of energy can vibrate. Condon's theory is based on the assumption that the molecule spends most of its time in an extreme position and that as a consequence the transitions between the extreme positions are the most probable. Since the $U(r)$ curve represents these extremes, transitions drawn between the upper and lower of two $U(r)$ curves of a molecule are according to the theory the most probable, and on an n', n'' diagram (cf. Fig. 2) they fall on a smooth curve roughly parabolic in form with the vertex near the origin of the system. If the constants and the function on which the $U(r)$ curves are based are correct, then the theoretical intensity distribution curve should pass through the most intense bands observed. The $U(r)$ function used by Condon in

Fig. 2. Intensities of band heads. The intensity of each band as listed in Table I is proportional to the diameter of the corresponding circle on the n', n'' diagram. Intensity distribution curves based on Morse's $U(r)$ function are plotted for two values of I_0'' . The observed distribution of band intensities agrees with $I_0'' = 15.0 \times 10^{-40} \text{ g cm}^2$.

developing his theory is a power series, and for computing purposes the polynomial composed of the first three terms is used. In the particular case of the CO molecule this polynomial is satisfactory only over a very small range of r near r_0 . An intensity curve using $I_0'' = 14.9$ appears in Condon's paper.¹⁸ This curve fits near the origin, but for quantum numbers higher than $n'' = 10$ the upper branch becomes concave upward while the trend of the bands in this region is concave downward.

Fortunately another form of $U(r)$ function is available¹⁹ which has the following properties: (a) when r is zero, U is very large, (b) when r is r_0 , U is at its only minimum, (c) when r is very large, U is asymptotic to D , the heat of dissociation, and (d) when the quantum theory is applied, the function yields the correct expression for the vibrational energy levels. This function is given by the expression

$$U = A + De^{-2a(r-r_0)} - 2De^{-a(r-r_0)},$$

where A is the constant which moves the entire curve up or down on the energy scale, D is the heat of dissociation, $a = 0.2454(M\omega_0 x)^{1/2}$, where M is

¹⁹ Morse, Phys. Rev. **34**, 57 (1929).

the reduced mass in terms of the atomic weights; and r and r_0 are nuclear separations, the latter corresponding to the special case of zero vibrational energy.

Theoretical intensity curves are drawn on Fig. 2 corresponding to $U(r)$ curves computed from the following constants:

	A	D	a	r_0
Initial	97500	32500	2.67	1.24
Final	91394	91394	2.29	1.09
	91394	91394	2.29	1.15

Curves corresponding to two values of the moment of inertia ($I_0'' = 15.0 \times 10^{-40}$ g cm², giving $r_0'' = 1.15A$, and $I_0'' = 13.5 \times 10^{-40}$, giving $r_0'' = 1.09$) appear on Fig. 2 because at the time the figure was first drawn Snow and Rideal's paper²⁰ giving $I_0'' = 15.0 \times 10^{-40}$ had not appeared and it seemed probable that the lower value of I_0'' was about right.^{9,21} The intensity curve corresponding to the lower value of the moment of inertia does not fit the observed bands very well, while the intensity curve corresponding to the larger value is an excellent fit, especially in the center of the diagram. For low quantum numbers the fit is really better than the figure would indicate because bands observed by others with a vacuum spectrograph are not shown since the diagram shows only the data of the author.

The intensity distribution among the bands of the fourth positive system is very distinct evidence in favor of the larger value of the moment of inertia if we assume that the $U(r)$ function given above is essentially correct. The evidence strongly favors this assumption and the intensity distribution can therefore be taken as good evidence from the electronic bands for the correctness of the infra-red value of the moment of inertia for the normal state. This represents a new and useful check on the value of this constant.

Babcock²² has estimated the prevalence of O¹⁶ relative to O¹⁸ as 1250:1. If we assume that C¹² has an atomic weight 12.000 and that C¹² and C¹³ are the only factors influencing the atomic weight (12.003) of carbon,²³ then they are prevalent in the ratio of 333:1. This calculation shows, in harmony with the experimental findings of King and Birge²⁴ that C¹³O¹⁶ is much more prevalent than C¹²O¹⁸ or C¹³O¹⁸. Therefore the calculated positions of several favorably located band heads of the C¹³O¹⁶ molecule have been examined on a heavily exposed plate, but no isotopic heads have been found. This does not cast doubt on the isotopic heads reported by Birge on the fourth positive absorption plates taken by Hopfield, but merely goes to show that absorption spectra show these faint bands more readily than do emission spectra.

I wish to express my appreciation for the advice and assistance of Professor R. S. Mulliken.

FINE STRUCTURE OF THE BERYLLIUM FLUORIDE BANDS

By F. A. JENKINS

DEPARTMENT OF PHYSICS, UNIVERSITY OF CALIFORNIA

(Received December 24, 1929)

ABSTRACT

Wave-length measurements of BeF bands.—New wave-length measurements have been made of the rotational lines of the BeF bands in the regions $\lambda\lambda 3009.5$ – 3026.3 , 2908.9 – 2927.8 , and 3126.1 – 3140.8 , which include all the stronger lines of the (0, 0), (1, 0) and (0, 1) bands. The source was a cored carbon arc run at atmospheric pressure. The Harvard 21-foot grating was used in the second order, giving a linear dispersion of 0.97 Å per mm and an effective resolving power of nearly 100,000. The wave-numbers of the lines in the six branches of each band are tabulated for rotational quantum numbers up to about $K=50$ in the R branches, 45 in the Q branches, and 30 in the P branches. Visual intensity estimates are also included.

Term analysis of BeF bands.—The rotational structure is found to be that characteristic of a ${}^2\Pi \rightarrow {}^2\Sigma$ electronic transition, with a relatively small value of $\Delta E/B$, +15.667, in the Π state. The combination relations among the lines of the (1, 0), (0, 0) and (0, 1) bands are satisfied within the experimental error in every case where exact agreement is to be expected. The R - Q , Q - P relations show a small combination defect, which is referred to Λ -type doubling in the initial state. This doubling is slightly greater for the levels involved in the low-frequency sub-band, and therefore it is assumed that the ${}^2\Pi$ state is normal. Rotational terms having the same K in the initial state draw rapidly together as the rotation increases, due to the loose coupling of the spin with the molecular axis. Quantitative agreement is obtained between the observed term-differences, ΔF , and their values calculated by the theoretical energy formulas derived by Hill and Van Vleck for the transition from case a to case b type of spin coupling. Equations capable of representing all the lines in a given band are deduced.

Constants of BeF molecule.—The following values for the more important molecular constants are obtained: $B^{(0)'} = 1.41060 \text{ cm}^{-1}$, $B^{(0)''} = 1.47928$, $\alpha' = 0.01610 \text{ cm}^{-1}$, $\alpha'' = 0.01685$, $D^{(0)'} = -8.301 \times 10^{-6} \text{ cm}^{-1}$, $D^{(0)''} = -8.209 \times 10^{-6}$, $\beta' = 1.060 \times 10^{-8} \text{ cm}^{-1}$, $\beta'' = 2.903 \times 10^{-8}$, $I_e' = (19.50 \pm 0.03) 10^{-40} \text{ g cm}^2$, $I_e'' = (18.59 \pm 0.03) 10^{-40}$, $r_e' = 1.390 \times 10^{-8} \text{ cm}$, $r_e'' = 1.357 \times 10^{-8}$, $\omega_e' = 1172.56 \text{ cm}^{-1}$, $\omega_e'' = 1265.62$, $x_e' = 0.007488$, $x_e'' = 0.007206$, $\nu_e = 33,233.61 \text{ cm}^{-1}$, $\Delta E = 22.10 \pm 0.1 \text{ cm}^{-1}$.

INTRODUCTION

BAND spectra are known for a large number of diatomic alkaline earth halides,¹ the most familiar being those of the fluorides, such as CaF. In general, the rotational structure of these bands is so finely spaced that there seems to be little hope of carrying out a detailed fine structure analysis, even

¹ For the experimental material on the alkaline earth halides, other than BeF, see H. Kayser, "Handbuch der Spectroscopie," Vols. 5, and 6, and S. Datta, Proc. Roy. Soc. 99A 436 (1921). General treatments of the relations between the electronic states, molecular constants, etc., have been given by R. Mecke, Zeits. f. Physik 42, 390 (1927) and by R. C. Johnson, Proc. Roy. Soc. 122A, 161, 189 (1929).

with spectrographs of the highest resolving power. The most favorable case for analysis is the lightest molecule of this class, BeF, for which, owing to its small moment of inertia, the spacing of the lines in a band should be great enough to permit almost complete resolution. A band system due to this molecule was first reported by Datta² in 1922. Its bands are shaded toward the red and lie completely in the ultra-violet, the head of the strongest occurring at $\lambda 3009.6$. Datta undertook a study of the fine structure of this band, and was able to identify three fairly regular series of lines. It is obvious, however, from an examination of his reproduction, and of the curves obtained, that the resolving power he used (third order of a 10-foot grating) was insufficient for a satisfactory quantum analysis of the band structure. Each of his series, as will appear in the present work, represents the blending of two or more true series. For the analysis to be reported here, new plates were taken, having a dispersion and actual resolution from 2 to 3 times greater than those attained by Datta. This comparatively small advantage has made possible a complete and satisfactory interpretation of the rotational structure.

The BeF bands were first considered from the standpoint of the quantum theory by Mulliken.³ Vibrational quantum numbers were assigned, and an equation derived for the frequencies of the heads, as measured by Datta. The molecule BeF was classed with a number of one-valence-electron emitters of band spectra, such as BO, CN, CO⁺, N₂⁺, the spectra of which appeared to be qualitatively similar. From such considerations, it was concluded that the ultra-violet BeF system represents a $^2\Pi \rightarrow ^2\Sigma$ electron jump, analogous to the α bands of BO, the red CN bands, etc. The latter are of the double double-headed type, the first head in each pair being formed by an *R*, and the second by a *Q* branch.⁴ Each of the BeF bands has only 3 heads, the first two forming a close pair of nearly equal intensity, and the third being somewhat weaker. It has therefore been assumed that the second and third heads are those of the *Q* branches, the second *R* head being too faint to be observed. On this view, the two *Q* heads should represent approximately the double origin of the band and from these $\Delta E \cong 35 \text{ cm}^{-1}$ for the $^2\Pi$ state. A revised interpretation of the formation of the heads has recently been given by Jevons.⁵ From a critical study of Datta's measurements, especially with regard to the variation of the mutual separations of the heads with vibrational quantum number, he concluded that the first pair of heads is formed by two closely parallel *R* branches and the third by one of two *Q* branches. Evidence for a second *Q* head was found on the writer's spectrograms early in the present work, but it appeared later during the analysis that this apparent head is merely a fortuitous accumulation of lines at the point in question.

In beginning the analysis of a band of complex structure, it is very desirable to have as a starting point an approximate idea of the type of band

² S. Datta, Proc. Roy. Soc. 101A, 187 (1922). An excellent reproduction of the band system as a whole is given.

³ R. S. Mulliken, Phys. Rev. 26, 561 (1925).

⁵ W. Jevons, Proc. Roy. Soc. 122A, 216 (1929).

structure, i.e. number of branches, approximate electronic separation, etc. According to the revised interpretation by Jevons, the rotational structure of the BeF bands should resemble that of the green MgH bands, where the electronic doublet separation is relatively small, and the corresponding branches of the two sub-bands draw rapidly together with increasing rotational quantum number. Bands showing this type of "rotational distortion" are fairly numerous⁶ and, as in BeF, three heads are usually observed, one of the Q branches not forming a head due to the distortion effect. Such a structure is characteristic of a ${}^2\Pi \rightarrow {}^2\Sigma$ or ${}^2\Sigma \rightarrow {}^2\Pi$ transition, in which the ratio of the doublet energy difference, ΔE , to the constant B , is small (i.e. less than about 20). A point strongly opposed to the previous interpretation, with $\Delta E/B$ large, appeared in the fact that, although the bands are closely grouped in sequences the distance from the R head to the origin would be extremely small (3 cm^{-1}). This would violate the rule of Birge and Mecke, according to which a small change in the vibration frequency during the transition is always accompanied by a small change in the moment of inertia. It therefore seemed probable that in BeF the $\Delta E/B$ is small. By postulating that the bands are of the MgH type, preliminary investigations of the structure⁷ showed that Jevons' scheme is essentially correct.

EXPERIMENTAL PROCEDURE

The spectrograms were obtained in the second order of the 21-foot grating at Harvard University, giving a dispersion of 0.97\AA per mm in the region investigated. An arc in air between carbon poles, both cored with a mixture of BeKF_3 and powdered carbon, gives not only the BeF, but also the BeO band system with considerable intensity in the flame surrounding the poles.⁸ Therefore, the BeO bands were also obtained on these plates. The rotational quantum analysis of the latter system has been given by Miss J. E. Rosenthal and the writer,⁹ and also independently by Bengtsson.¹⁰ In the former article will be found a brief description of the experimental details pertaining to the spectrograms used in the present investigation, since the BeF and BeO spectra were photographed simultaneously. Two sets of plates were of use for our purpose, one showing the stronger sequence $\Delta v = 0$ ¹¹ with the best possible resolution (slow, fine-grained plates) and another on which the 0 sequence is considerably over-exposed, but the sequences $+1$ and -1 are of satisfactory

⁶ R. S. Mulliken, Phys. Rev. **32**, 388 (1928).

⁷ The main results embodied in the present article were given in a paper before the American Physical Society, Washington Meeting, April, 1929. Cf. Phys. Rev. **33**, 1090 (1929) (Abstract).

⁸ Jevons, ref. 5, finds that the oxide bands are relatively stronger in the outer part of the flame.

¹¹ The nomenclature used here conforms with the revised system recently proposed (Mulliken, private communication). In this v represents the vibrational quantum number, formerly n .

intensity. The first heads of the three sequences are, according to Mulliken's assignment: $\lambda 3009.582$ (0), $\lambda 2908.994$ (-1) and $\lambda 3126.116$ (+1). Doublets with a separation of 0.04\AA are resolved on these plates. The iron arc comparison spectrum shows no relative displacement on the two sets. An enlargement of part of the 0 sequence from the first set is shown in Fig. 1, accompanied by a Fortrat diagram of the (0, 0) band, according to our complete analysis.

In order to take full advantage of the combination principle, it was necessary to study bands which would yield agreements in the term-differences of

Fig. 1. (0, 0) band of BeF. The spectrum has been enlarged to practically the same scale as the diagram, but the correspondence of the lines with points on the diagram is not exact throughout, because the latter is on a scale of frequencies.

both the initial and the final states. Accordingly, wave-length measurements were made of the lines in the first band of each of the three above-mentioned sequences, i.e. in the (0, 0), (1, 0) and (0, 1) bands. The secondary Fe wave-length standards given by Fabry¹² were used throughout. The measurements included every line in each sequence as far as the first head of the third band in that sequence. This was necessary because, as will be apparent in Fig. 1, many lines of the first band are intermingled with those of the second. In

¹² Ch. Fabry, Int. Crit. Tables, Vol. V, p. 275.

general, our wave-lengths agree well with those of Datta.² Table I gives the wave-numbers in vacuum of all lines assigned to the above three bands. A large number of measured lines belonging to the second bands of the sequences are not given, because they represent only certain parts of these bands and would be of little value for the present purpose. Although there is an element

of arbitrariness in reporting the data in this way, that is in giving only lines assigned to the P , Q and R branches, it should be emphasized that every line of measurable intensity up to the head of the second band is accounted for and included in Table I. It is true that, due to the complexity of the structure blends of two or more lines are frequent, and the same wave-number often occurs several times in the table. It will be shown below, however, that this

does not materially detract from the certainty of our interpretation of the band structure. Following each wave-number in Table I, a superscript gives the number of times a given value appears, or in other words the number of lines of the band coinciding so closely as to be unresolved and measured as a single line. The last number gives a rough measure of the intensity, on a scale 0 to 5, from eye estimates made during the measurements. These are only strictly comparable for lines near together. The letter *d* indicates a particularly wide or diffuse line. Thus, for example, the line $R_1(26)$ in the (0, 0) band

is given as $33,211.77^4 3d$, since it is a diffuse line formed by the near coincidence of $R_1(26)$, $R_2(28)$, $R_1(14)$, $R_2(10)$, and is of intensity 3 on the scale employed. Regularities in the intensities, as well as the significance of the designations R_2 , R_1 , K , etc., will be discussed below in connection with the quantum analysis.

INTERPRETATION OF THE DATA

Solution of band structure. In attacking the problem of sorting out the various branches, it was noticed from the outset that a short series of very strong lines appears in the region between the second and third heads of each band, and another at some distance beyond the third head (See Fig. 1). These lines are sharp only for a few members, becoming diffuse and soon separating into doublets at each end. Since the separation of adjacent lines in the first of these series is slightly less than that of the close double head, which is that formed by the branches R_2 and R_1 according to the provisional interpretation, it appeared that these strong lines must have about the separation of the so-called "natural" doublets of the R branch. These doublets are formed by pairs of lines with the same value of K^{13} in the $^2\Pi$ state, and the components approach each other as the rotation increases to the point where the spin axis becomes coupled nearly as in Hund's case b .⁶ With the doublets spaced so that the second component of one falls on the first component of the next, the above-mentioned series show exactly the aspect they should. This is the strongest of the series identified by Datta. Similarly, the second series is formed by an analogous coincidence in the doublets of the Q branch. With this opening, it was a simple matter to identify two series of doublets, those of the R and Q branches. The approximate assignment of rotational quantum numbers to these lines in the $(0,0)$ band was then obtained in the following way. The first differences of the *mean* wave-numbers for the Q doublets were plotted against an arbitrary numbering, and extrapolated to zero spacing. This gives roughly the position of the band origin, ν_0 , and a revised numbering of the Q lines, (starting with 1 at the point of convergence) which is correct to one or two units. The slope of the line is 2 ($B' - B''$). Next, taking the mean values of the R doublets, we use the formula for the distance H from the (mean) R head to the origin.

$$H = B' - \frac{(B')^2}{B' - B''}.$$

One thus obtains approximate values of both B' and B'' , and also an idea of the assignment of quantum numbers to the R lines, from the relation $K_{head} = B'/(B' - B'')$, to the nearest whole number. The method of working with mean values of the natural doublets recommends itself for such preliminary work, since these follow very nearly the simple relations in a band with singlet R , Q and P branches.

¹³ K is used here for the resultant of Λ and N , where Λ measures the effective component of the resultant orbital angular momentum along the nuclear axis, and N the angular momentum of the nuclei (K formerly j_k , Λ formerly σ_k , N formerly m). Also J will here replace the former j (quantum number of the total angular momentum).

To be certain of the true K assignment, recourse must be had to the combination principle. To this end, the above process was repeated for the (1,0) band, and the R and Q series identified, with their approximate numbering. By suitably shifting the relative numbering in these series, both in the (0, 0) and (1, 0) bands, two sets of $R-Q$ differences were found which agreed throughout the observed range. These represent the combination differences $R_m(K) - Q_m(K+1) \cong \Delta_1 F''(K)$, of the final state $v'' = 0$. In a $^2\Sigma$ state, one has¹⁴

$$\Delta_1 F''(K) = 2B''(K+1) + 4D''(K+1)^3 + \dots, \quad (1)$$

where D can be approximated by the theoretical relations given on p. 327. Correcting for the cubic term, which is small, there results a series of quantities practically linear in K , which may be used to determine the final true assignment of K values. In agreement with the theoretical requirement for an odd molecule, the K values appeared definitely to be whole numbers. These $R-Q$ combination agreements obtained between the (0, 0) and (1, 0) bands were afterwards proved to be unique by the method of Pomeroy.¹⁵ This is a systematic procedure for trying all possible relative numberings for the four branches,¹⁶ which eliminates the possibility of a fortuitous agreement yielding false combination differences. Three other possible assignments were indeed found, with the short range of lines then available, but all of these gave a relative numbering far outside the range of possible error in the preliminary assignment reached by the method first described. Considering finally the (0, 1) band, it was found that with but a slight shift in the preliminary numbering, satisfactory equality could be obtained with the differences $R_m(K) - Q_m(K) = \Delta_1 F'_m(K)$ from the (0, 0) band.

In identifying the remaining lines of the bands, a convenient procedure described by Loomis and Wood¹⁷ was followed. Having the lines of a portion of a given branch, one derives an empirical formula in K to fit the wave-numbers of these members, using again the mean value of each doublet. The deviations of all observed lines from this equation are then plotted; at least of all which lie within a few cm^{-1} on either side of each calculated value. Such a diagram is shown in Fig. 2 for the Q lines of the (0, 0) band. The series stand out clearly among the extraneous lines, and the proper line to choose in each case is apparent. The method has the added advantage that any other series with approximately the same spacing as those used, such as the so-called "satellite" series, will reveal their presence. By this means, the Q branches were extended to small values of K , the low-frequency components converging in the third head, and the high-frequency components extending into the comparatively simple portion beyond this head. The low K lines of the R branches could then be found by adding the appropriate combination

¹⁴ This expression for $\Delta_1 F''$, the difference between adjacent rotational terms of the lower state, is derived directly from the term formula, Eq. (3) below.

¹⁵ W. C. Pomeroy, Phys. Rev. **29**, 59 (1927).

¹⁶ I am indebted to Mr. S. W. Nile, New York University, for performing this lengthy calculation.

¹⁷ F. W. Loomis and R. W. Wood, Phys. Rev. **32**, 223 (1928).

differences $\Delta_1 F''(K)$, computed from Eq. (1), to the mean values $Q_m(K+1)$. Adding and subtracting half the doublet separation for $Q(K+1)$, the R lines going up to the head were identified as a series of weak lines not previously assigned. The location of this series was clearly not that to be expected if the doubling of $R(K)$ was assumed to be the same as that of $Q(K)$. This is a proof that the large doubling is in the initial state, and that the transition is ${}^2\Pi \rightarrow {}^2\Sigma$, and not ${}^2\Sigma \rightarrow {}^2\Pi$. This statement will be evident if one refers to the energy level diagram of Fig. 3.

Fig. 2. Deviations of lines in the (0, 0) band from the approximate formula for the mean wave-numbers of the Q doublets: $Q_m(K) = \nu_0 - B' + (B' - B'')(K + \frac{1}{2})^2 + (D' - D'')(K + \frac{1}{2})^4 = 33,185.80 - 0.0685(K + \frac{1}{2})^2 - 0.0920 \times 10^{-6}(K + \frac{1}{2})^4$. The curves give the deviations of the theoretical values of $Q(K)$, calculated by Eq. (11).

The R branches are comparatively free from overlapping by extraneous lines, but their extension to values of K lower than that of the head could not be satisfactorily done in the weaker bands (0, 1) and (1, 0), especially the latter, where the value of K_{head} is smallest. Graphs of the type shown in Fig. 2 were used to identify the Q and P branches in all three bands. The preliminary equation for finding the P branches was based on the approximate relation

$$P_m(K) = Q_m(K-1) - [R_m(K-1) - Q_m(K)]. \quad (2)$$

This is strictly true only in the absence of the well-known Λ -type doubling associated with ${}^2\Pi$ states. A systematic deviation from the predicted positions of the P lines was in fact found, of nearly the same magnitude for the components P_2 and P_1 . The observed lines were slightly displaced toward lower frequencies from the values calculated by Eq. (2).

Analysis of rotational terms. The lines given in Table I comprise six branches for each band, three of which, R_1 , Q_1 and P_1 , are to be correlated with terms of the initial and final states in which the spin vector, $S=1/2$, when completely uncoupled from the nuclear axis, stands parallel to the resultant vector K of the orbital and nuclear angular momenta. Similarly, for R_2 , Q_2 and P_2 , S is anti-parallel to K in both states. In the lower state, ${}^2\Sigma$, there is no component, Λ , of the orbital angular momentum along the molecular axis, and hence no interaction of the spin with this axis, even at very low values of K . The rotational terms may then be represented by

$$F_2(J) = BK(K+1) + D[K(K+1)]^2 + \dots \quad (3)$$

In this case each level is a degenerate pair, $F_2(K-1/2)$ coinciding with $F_1(K+1/2)$, where F_1 and F_2 designate terms having S parallel and antiparallel to K , respectively. If this degeneracy is removed by the rotation, we have ρ -type doubling, but in the present case no evidence for this doubling was found, as explained below, under *Intensities*.

In the initial state, ${}^2\Pi$, the situation is more complicated. At high speeds of rotation, the condition is almost the same as in the ${}^2\Sigma$ case, levels of the same K coming close together. In Fig. 3, the tendency of these levels to approach each other is evident, even when K is relatively small. With decreasing K , the corresponding levels diverge more and more, as the interaction of the spin with the molecular axis becomes stronger. In the limit of no rotation if the doublet is normal, S is anti-parallel to Λ for F_1 terms (${}^2\Pi_{1/2}$), and parallel for F_2 (${}^2\Pi_{3/2}$). If it is inverted, S is parallel to Λ for F_1 terms (${}^2\Pi_{3/2}$) and antiparallel for F_2 (${}^2\Pi_{1/2}$). In either case the set of lower energy is designated F_1 . Two methods are available for distinguishing a normal from an inverted doublet. There should be more missing lines in the ${}^2\Pi_{3/2}$ than in the ${}^2\Pi_{1/2}$ sub-band. In the present case these could not be determined, due partly to the numerous cases of superposition, and partly to the faintness of the first few lines in a branch. An alternative criterion is available in the magnitude of the Λ -type doubling. In case *a*, this is always much larger for ${}^2\Pi_{1/2}$ than for ${}^2\Pi_{3/2}$.¹⁸ It was impossible in our case to detect this doubling for low values of K , and at larger values the type of coupling approaches case *b* rapidly. Van Vleck has shown¹⁸ that in the strict case *b* the Λ -type doubling should be equal for ${}^2\Pi_{1/2}$ and ${}^2\Pi_{3/2}$. That this is not exactly true in the BeF bands, even for very large K , can be most directly shown by comparing the natural doublet separation for $Q(K)$ with that for $R(K-1)$ and $P(K+1)$. The Q branch separations are noticeably smaller, which shows that the Λ -type doubling is greater in the F_1' states (see Fig. 3). The difference is not great, however, and is only

¹⁸ J. H. Van Vleck, Phys. Rev. 33, 467 (1929). R. S. Mulliken, Phys. Rev. 33, 507 (1929).

considerable for high K values, as will be seen in Fig. 4, which represents graphically the course of these natural doublet separations. In the absence of confirmatory evidence from the missing lines, it seemed best to assume that the $^2\Pi$ state is normal.

Fig. 3. First few rotational terms in the initial and final states $v=0$, drawn to scale according to Eqs. (3) and (4). The transitions shown by the vertical arrows give the natural doublets $R(K-1)$, $Q(K)$ and $P(K+1)$, (here $K=4$) which have the same doublet separation, except for slight differences in the A-type doubling for $F_1'(K)$ and $F_2'(K)$. The latter doubling, to be visible, is magnified 100-fold.

The effect of the transition from case a at low rotational speeds to case b at high speeds upon the energy formula for doublet states was first studied quantitatively by Kemble.¹⁹ The resulting equations were tested with the OH

¹⁹ E. C. Kemble, Phys. Rev. 30, 387 (1927).

bands, and gave excellent agreement except at the lowest values of K . Slight discrepancies were to be expected, because the formulas were based on the old quantum theory. More recently, Hill and Van Vleck,²⁰ using the new mechanics, have obtained a convenient closed formula for the energy throughout the transition from case a to case b , applicable to both normal and inverted doublets. Aside from their statement that somewhat better agreement with experiment is obtained in the case of OH than found by Kemble, this formula appears not to have been applied in any specific case. It is therefore desirable to see how well it is capable of giving the observed rotational terms in Be F. Denoting by λ the ratio $\Delta E/B\Lambda$, and introducing the term in $D[K(K+1)]^2$ appropriate to case b (since this is appreciable only at higher values of K) the equations of Hill and Van Vleck may be written

$$F_2(J) = B(K^2 - \Lambda^2) + \frac{B}{2} [4K^2 + \lambda(\lambda - 4)\Lambda^2]^{1/2} + D[K(K+1)]^2 + \dots$$

$$F_1(J-1) = B(K^2 - \Lambda^2) - \frac{B}{2} [4K^2 + \lambda(\lambda - 4)\Lambda^2]^{1/2} + D[K(K-1)]^2 + \dots$$
(4)

The J in each case is that appropriate to the value of K in the same equation, that is, $J_2 = K - 1/2$, $J_1 = K + 1/2$. For a $^2\Pi$ state, $\Lambda = 1$ always. The constant $B = h/8\pi^2 Ic$ is best determined from the initial state combination differences at relatively high K , where case b is approximated. Thus, one has

$$\Delta_1 F'_m(K) = 2B'(K+1) + 4D'(K+1)^3 + \dots$$
(5)

Taking $\Delta_1 F'_m(K)$ as the mean of the combination differences $R_m(K) - Q_m(K)$ and $Q_m(K+1) - P_m(K+1)$, to eliminate the effect of Λ -type doubling, the constants²¹ $B^{(0)'}$ and $B^{(1)'}$, were evaluated by least squares from the ΔF 's between $K=20$ and 30. For this purpose, the effect of the term in $(K+1)^3$ was first allowed for by using the accurate values of $D^{(0)'}$ and $D^{(1)'}$ obtained from the theoretical relations²²

$$D^{(v)} = D_e + \beta(v + \frac{1}{2})$$

$$D_e = -4B_e^3/\omega_e^2$$

$$\beta = \frac{\alpha^2}{6\omega_e} + \frac{20\alpha B_e^2 - 32x_e B_e^3}{\omega_e^2}$$
(6)

The equation for β is taken from Kemble's work,²³ and is in a more convenient form than that given by Pomeroy.¹⁵ The ω_e and x_e were taken from Jevons' work,⁵ and α was approximated from preliminary results. An analogous com-

²⁰ E. L. Hill and J. H. Van Vleck, Phys. Rev. 32, 250 (1928).

²¹ The vibrational quantum number v to which a constant refers will be indicated as a superscript, in parentheses.

²² The subscript e indicates that the constant refers to the *equilibrium* position of the nuclei ($v = -\frac{1}{2}$).

²³ E. C. Kemble, Jour. Opt. Soc. Am. 12, 1 (1926). The possibility of getting this convenient expression for β was kindly called to my attention by Prof. R. T. Birge.

putation with $\Delta_1 F''$, using Eq. (1), gave the constants $B^{(0)''}$ and $B^{(1)''}$ of the final state.

Since it was impossible to obtain observed values of the separations of the lowest levels, it was necessary to choose a value for λ such that Eqs. (4) fit the

Fig. 4. Separation of the natural doublets as a function of rotational quantum number. In (a) the curve gives the theoretical separations from Eq. (7). The curve in (b) gives the best representation of the empirical separations in the Q branches, to show their divergence from those in the R and P branches at high values of K .

data for higher K most exactly. If this can be done, we have the electronic difference in the upper state for zero rotation, ΔE , since by definition $\lambda = \Delta E/B$. Instead of calculating the actual $F(J)$ values, it is more convenient to use the expression derived from Eqs. (4) for the natural doublet separation.²⁴

²⁴ The equation for Δ given by Hill and Van Vleck applies not to the actual doublets, but to a mean value of the separation for two adjacent ones.

$$\Delta = F_1'(K) - F_2'(K) = B' \left[\frac{1}{2} \{ 4K^2 + \lambda(\lambda - 4) \}^{1/2} + \frac{1}{2} \{ 4(K+1)^2 + \lambda(\lambda - 4) \}^{1/2} - 2(K + \frac{1}{2}) \right] \cong B' \left[\{ 4(K + \frac{1}{2})^2 + \lambda(\lambda - 4) \}^{1/2} - 2(K + \frac{1}{2}) \right]. \quad (7)$$

The best representation of Δ from the Q branches, shown graphically in Fig. 4(a) is obtained with $\lambda = +15.667$, assuming a normal doublet. If the doublet is taken as inverted, an equally good fit is obtained with $\lambda = -11.667$. With $B' = 1.4108$ (see p. —), this gives for the electronic separation in the $^2\Pi$ state $\Delta E = +22.10$ cm $^{-1}$ if it is normal, -16.46 if inverted. A change of ± 0.1 cm $^{-1}$ in these quantities makes the agreement with the observed Δ curves definitely less exact.

The rotational terms, $F(J)$ are not found directly from the spectrum, but only their differences, ΔF . Table II contains these quantities for all cases in which agreements between different sets are to be expected. Strict equality should only be found for corresponding differences in two bands with a common vibrational state, for example $R_2(K) - Q_2(K)$ in the (0, 0) and (0, 1) bands. The agreement of the differences $R - Q$ with $Q - P$ is only approximate, due to the Λ -type doubling in the initial state. It seemed best, for purposes of comparison with the theory, to eliminate the effect of this

doubling by defining the ΔF 's in terms of the centers of the doublet levels. Reference to Fig. 3 will show that to obtain these ΔF 's, the differences between actual lines must be corrected by an amount proportional to the

combination defect $[R(K) - Q(K+1)] - [Q(K) - P(K+1)]$, which we will call $2\delta F$. According to the theory,¹⁸ the Λ -type doubling, and hence the combination defect, should be proportional to $(J + \frac{1}{2})^2$. Graphs of $2\delta F$ against J for F_1' and F_2' states gave curvessimilar to that obtained by Loomis and Wood¹⁷ for the Na_2 bands, in which the defect could be satisfactorily represented as proportional to $(J + \frac{1}{2})^2$. Hence a simple method of taking the Λ -type doubling into account in the energy formulas is to give slightly different values of B to the F_A and F_B levels. Their difference can be found from the combination defect by the relation¹⁷

$$2\delta F = [F_A'(J+1) - F_B'(J+1)] + [F_A'(J) - F_B'(J)] \\ \cong 2[F_A'(J + \frac{1}{2}) - F_B'(J + \frac{1}{2})] = 2(B_A' - B_B')(J + \frac{1}{2})^2. \quad (8)$$

The values of $B_A' - B_B'$ obtained in this way were, for F_1' states, $+0.00046$, and for F_2' , $+0.00028$. The corrections, δF_1 and δF_2 , to be applied to the

Fig. 5. Comparison of $\Delta_1 F'(J)/(J+1)$ with the theoretical curves (Eq. (10)). Data from the (0, 0) band.

combination differences to obtain the quantities $\Delta_1 F'$ are indicated above each column in Table II.

The formula for $\Delta_1 \hat{F}'$ may be found from Eqs. (4) as follows:

$$\frac{dF_i(J)}{dJ} = \Delta_1 F_i(J - \frac{1}{2}) = 2B'(J + \frac{1}{2}) [1 \pm (4(J + \frac{1}{2})^2 + \lambda(\lambda - 4))^{-1/2}] \\ + 4D'(J + \frac{1}{2} \pm \frac{1}{2})^3 + \dots \quad (9)$$

The upper sign applies to F_2 and the lower to F_1 . This formula was tested in several cases, and agreed with the observed ΔF 's within a few hundredths cm^{-1} . For a graphical comparison of the theory with the empirical results, it is more convenient to divide the ΔF 's throughout by $(J+\frac{1}{2})$. Thus, to a close approximation

$$[\Delta_i F_i'/(J+\frac{1}{2})]/(J+\frac{1}{2}) = 2B'[1 \pm \{4(J+\frac{1}{2})^2 + \lambda(\lambda-4)\}^{-1/2}] + 4D'(J+\frac{1}{2} \pm \frac{1}{2})^2. \quad (10)$$

In Fig. 5 are plotted the observed quantities $\Delta F/(J+1)$ against J , and the curve represents the theoretical values from Eq. (10). Although systematic discrepancies are evident, especially at high J , it is probable that these could be somewhat reduced by slight adjustments of the constants. This was not attempted, but it is clear that the theory accounts remarkably well for the rather complicated variation of the ΔF 's. Not only do the two sets draw together in the proper way, but they show the expected downward trend at large J values due to the term in D' .

The term-formulas (4) are surprisingly simple, considering the complexity of the uncoupling phenomenon involved. They permit the representation of all the lines of a complex band of this kind by comparatively compact and convenient formulas. Taking Eqs. (3) for the terms of the lower state, and Eqs. (4) for those of the upper, and forming the appropriate differences for the several branches, one obtains expressions of the form:

$$\nu = a + bK + c/2[4K^2 + \lambda(\lambda-4)]^{1/2} + dK^2 + eK^3 + fK^4. \quad (11)$$

TABLE III. Values of coefficients for each branch.

Lines	a	b	c	d	e	f
$R_2(K-1)$	$\nu_0 - B_2B'$	B''	B_2B'	$B_2B' - B''$	$2(D' + D'')$	$D' - D''$
$R_1(K-2)$	$\nu_0 - B_1B' - 2B''$	$3B''$	$-B_1B'$	$B_1B' - B''$	$-2(D' - 3D'')$	$D' - D''$
$Q_2(K)$	$\nu_0 - B_2A'$	$-B''$	B_2A'	$B_2A' - B''$	0	$D' - D''$
$Q_1(K-1)$	$\nu_0 - B_1A'$	B''	$-B_1A'$	$B_1A' - B''$	0	$D' - D''$
$P_2(K+1)$	$\nu_0 - B_2B' - 2B''$	$-3B''$	B_2B'	$B_2B' - B''$	$2(D' - 3D'')$	$D' - D''$
$P_1(K)$	$\nu_0 - B_1B'$	$-B''$	$-B_1B'$	$B_1B' - B''$	$-2(D' + D'')$	$D' - D''$

The coefficients to be used for each branch are given in Table III. The origin, ν_{00} of the (0, 0) band was found by applying these equations to several lines of each branch, the average of a number of consistent values being 33,187.21 cm^{-1} . Eq. (11), taken in connection with our final values of the constants, listed below, represents all the lines of the (0, 0) band quite accurately, the largest consistent deviation being about 0.2 cm^{-1} . Errors of this size would not be noticeable in a diagram on the scale of that in Fig. 1. Small systematic trends are apparent, however, when the lines are represented graphically by the method illustrated in Fig. 2. Nevertheless, the formulas reproduce the observed lines to the same order of accuracy as do the more familiar ones applicable to bands of simpler structure.

The molecular constants resulting from the present study of the band structure are given in Table IV. All are expressed in cm^{-1} units.

TABLE IV. *Molecular constants.*

Initial state, $^2\Pi$ (normal)	Final state, $^2\Sigma$
$\Delta E = 22.10$	
$B_{1A}^{(0)} = 1.41083$	
$B_{1B}^{(0)} = 1.41037$	$B^{(0)} = 1.47928$
$B_{2A}^{(0)} = 1.41074$	
$B_{2B}^{(0)} = 1.41046$	
$\alpha = B^{(0)} - B^{(1)} = 0.01610$	0.01685
$D^{(0)} = -8.301 \times 10^{-6}$	-8.209×10^{-6}
$\beta = D^{(1)} - D^{(0)} = 1.060 \times 10^{-8}$	2.903×10^{-8}

Defining B_e as the value of $h/8\pi^2 I_e c$ for the non-vibrating molecule, we have $B^{(v)} = B_e - \alpha(v + \frac{1}{2})$, whence $B_e = B^{(0)} + \alpha/2 = 1.48770$ in the lower state. Using the relation $I_e = 27.66/B_e$ given by Birge,²⁵ the equilibrium value of the moment of inertia in the less excited state becomes $(18.59 \pm 0.03) 10^{-40} \text{ g cm}^2$, and the corresponding internuclear distance 1.357\AA . In the more excited state, these quantities are, respectively, $(19.50 \pm 0.03) 10^{-40} \text{ g cm}^2$ and 1.390\AA .

Intensities. The intensity in each branch rises to a maximum at about $K=20$, and then falls off slowly in the usual way. On our plates, the first few lines were too faint to be observed. The two components of each natural doublet are, as far as can be judged, of equal intensity. Because of the great amount of overlapping in the P branches and the outer part of the Q branches it is difficult to compare the relative intensities of the various branches. By considering only the weaker lines in the regions where blends are frequent, an approximation can be made, however. The P branches have about the same intensity as the R —perhaps slightly less. The Q lines are much stronger, with about twice the intensity of the R lines of the same rotational quantum number.

Mulliken's scheme⁶ for $^2\Pi \rightarrow ^2\Sigma$ transitions predicts certain satellites of the strong branches, and two further branches, for which $\Delta K = \pm 2$. All of these should be relatively weak when $\Delta E/B$ is small. In the absence of ρ -type doubling in the final state, his satellites $^R Q_{21}$ and $^Q P_{21}$ coincide with the strong branches R_2 and Q_2 respectively. Similarly, $^Q R_{12}$ and $^P Q_{12}$ coincide with Q_1 and P_1 . Our failure to observe these satellites is the most important evidence for the absence of appreciable ρ -type doubling in the $^2\Sigma$ state of BeF. Of Mulliken's double R - and double P -form branches, which may be called S_{21} and O_{12} , the former is definitely absent, and therefore almost certainly the latter as well. Our graphical investigations by the method of Fig. 2 show no evidence for the presence of the satellites Q_{2B2A} and Q_{1B1A} , which violate the selection principle for Λ -type doubling, but which are, however, found in the OH bands.

Vibrational structure. Jevons⁵ has derived the following equations to represent the heads of some 45 bands of this system.

²⁵ R. T. Birge, Phys. Rev. Supplement 1, 62 (1929).

$$\begin{aligned}
 R_2 \text{ heads: } \nu &= 33,217.3 + 1153.3\nu' - 5.88\nu'^2 - 1247.1\nu'' + 11.21\nu''^2 - 4.92\nu'\nu'' \\
 R_1 \text{ heads: } \nu &= 33,214.3 + 1153.9\nu' - 5.67\nu'^2 - 1247.1\nu'' + 11.50\nu''^2 - 5.36\nu'\nu'' \\
 Q_1 \text{ heads: } \nu &= 33,179.9 + 1163.8\nu' - 8.78\nu'^2 - 1256.5\nu'' + 9.12\nu''^2.
 \end{aligned}$$

The coefficients in the third equation, except the constant term, apply equally well to the band origins, since the head of the Q_1 branch occurs at a very small value of K . Assuming that the vibrational constants are the same in ${}^2\Pi_{3/2}$ and ${}^2\Pi_{1/2}$, the variation with ν of the distance from the Q_1 head to the origin is probably negligible. Inserting the constant, ν_0 , evaluated above, the equation for origins becomes

$$\nu_0 = 33,187.21 + 1163.8\nu' - 8.78\nu'^2 - 1256.5\nu'' + 9.12\nu''^2 \quad (12)$$

The vibration frequency for infinitesimal amplitudes is, accordingly, $\omega_e = \omega^{(0)} + x\omega^{(0)} = 1265.62$ in the final state, and 1172.58 in the initial state. The electronic frequency, ν_e of the system-origin is obtained as the constant term when Eq. (12) is transformed to express ν_0 as a function of $(\nu + \frac{1}{2})$. We find $\nu_e = 33,233.61$.

Morse²⁶ has recently found an empirical relation connecting the constants $\omega^{(0)}$ and $r^{(0)}$, which is useful as a check on the correctness of our analysis. According to this rule, $\omega^{(0)}r^{(0)} = 3000 \pm 120 \text{ Å}^3/\text{cm}$. In the present case the product is 3159 and 3176 in the upper and lower states, respectively. Another important rule, due to Birge²⁷ requires that $2xB^{(0)}/\alpha = 1.4 \pm 0.2$. From our constants, this ratio for BeF is 1.32 in the upper state, and 1.27 in the lower.

CONCLUSIONS

This is the first analysis of a band structure of the contracting doublet type in a spectrum other than that of a diatomic hydride. Due to the much closer spacing of the lines (the moment of inertia is 13 times that of OH), the actual resolving power available was not far above the minimum required for an unambiguous proof of the structure by the application of the combination principle. In view of the various agreements with the theory, and especially of the graphical proofs of the reality of the different line series, it is thought that our results are justified in all their more essential respects. Several investigators^{1,5} have drawn conclusions concerning the electronic states of other alkaline earth halides from a study of the positions and intensities of the heads in the numerous band systems of these molecules. As stated above, these systems appear to be beyond the reach of our present spectrographs, as far as the rotational structure is concerned. It should be emphasized that bands due to entirely different types of electronic transitions may show an almost identical gross structure. For example, the BeF bands described here show very nearly the same relative spacing and intensity of the three heads in each band as do the blue-green TiO bands recently analysed by Christy,²⁸ although the states involved are even of a different mul-

²⁸ A. Christy, Phys. Rev. **33**, 701 (1929).

tiplicity; the transition is $^3\Pi \rightarrow ^3\Pi$. Therefore, unless one brings every available type of evidence to bear, it seems that conclusions based on a study of the band heads alone must be regarded as highly speculative.

The $^2\Pi \rightarrow ^2\Sigma$ system of BeF constitutes the entire known spectrum of this molecule. Although it has not as yet been obtained in absorption, it appears probable, from analogy with the iso-electronic molecule CN, that the $^2\Sigma$ state is the normal electronic configuration. The band systems in the visible region due to a number of other alkaline earth halides have been found in absorption.²⁹ Mulliken³⁰ has given a provisional assignment of quantum numbers to the individual electrons in BeF as follows: in the $^2\Sigma$ state, $(2s\sigma)^2 (3p\sigma)^2 (2p\pi)^4 (3s\sigma)$, and in the $^2\Pi_i$ state, $(2s\sigma)^2 (3p\sigma)^2 (2p\pi)^4 (3p\pi)$. The assignment given for $^2\Sigma$ is identical with that for the $^2\Sigma$ state (normal state) of BO, CN and CO^+ . For the $^2\Pi$ state, however, the arrangement differs from that proposed for the inverted $^2\Pi$ states of BO, etc., which are designated $(2s\sigma)^2 (3p\sigma)^2 (2p\pi)^3 (3s\sigma)^2$, $^2\Pi$. This difference in interpretation is based on the fact that ΔE in the $^2\Pi$ state is much smaller for BeF than for the others ($\Delta E = 126, 56, 126$). No contradiction to Mulliken's conclusions is therefore contained in our assumption of a normal $^2\Pi$ state, with $\Delta E = 22.10$.

In conclusion, it is a pleasure to acknowledge several valuable suggestions in connection with this work from Professors R. T. Birge and R. S. Mulliken, as well as assistance in the measurements and computations from Mr. S. W. Nile and Professor F. W. Doermann.

RELATIVITY AND AETHER DRIFT¹

By W. F. G. SWANN

BARTOL RESEARCH FOUNDATION OF THE FRANKLIN INSTITUTE

(Received January 10, 1930)

ABSTRACT

While aether drift experiments originally suggested the line of thought which led to the formulation of the restricted theory of relativity, it would seem that the fundamental significance of that theory does not depend primarily upon these experiments. The most logical origin of the transformation of the restricted theory is to be found as a special case of the general theory, and the purpose of the present paper is to show how, with this in view, the fundamental working content of the restricted theory, the invariance of laws under the Lorentzian transformation, is something which has no fundamental relation to the question of whether the aether drift experiments do or do not give a positive result.

THE general belief thirty years ago that the Michelson-Morley-Miller experiment gave a "null" result led to a formulation of the restricted theory of relativity in a form in which the actual space and time measures of observers in two relatively moving systems S and S' were considered, and in which postulates were stated and a law of transformation from one set of measures to the other was derived such as to insure that both observers would measure the same velocity c in all directions for the velocity of light. The transformations are the well-known transformations first derived by Larmor and Lorentz in electromagnetic theory, and are of the form

$$x' = \beta(x - vt) ; y' = y ; z' = z ; t' = \beta \left(t - \frac{v}{c^2} x \right) \quad (1)$$

where
$$\beta = \left(1 - \frac{v^2}{c^2} \right)^{-1/2} .$$

The desire to provide for the null effects in other experiments which had been attempted and which might yet be attempted to detect the earth's "absolute motion" led to the further postulate that the same transformation of measures which served to conceal from the observers any difference as regards the propagation of light in their two systems would also serve to conceal from them any analogous difference as regards any other experiments which they might perform. The postulate was completely provided for by the more widely embracing postulate that the laws of nature² are invariant under the Lorentzian transformation (1), at least this is the case if the two sets of

¹ Presented at the Chicago Meeting of the American Physical Society, November 30, 1929

² The more detailed significance of the content of this statement will be discussed in an article "Relativity and Electrodynamics" now in process of publication in the Physical Review Supplement.

coordinates specified in (1) correspond to the actual measures of observers in the two systems. There are, in fact, two aspects to the restricted theory of relativity as usually understood. The first, which we shall call (*A*), which takes (1) as relations between the actual measures of observers in the two systems, and the second which we shall call (*B*) which concerns itself with the form of physical laws as expressed in the first instance, at any rate, in *one* system of coordinates. In its general form, aspect *B* may be said to imply that "There exists a way of assigning numbers to identifiable points in space-time (there exists a set of coordinates) such that if the laws of nature are expressed in terms of them, they will be found to be invariant under the Lorentzian transformation (1); so that if there exists one set of coordinates in which the statement is true, there exists an infinity of all others, obtainable from the first by Lorentzian transformations, in which the statement is also true." But there will also be a multifold infinity of other sets of coordinates such that if the laws be expressed in terms of these, the statement will not be true.

The test of the forms of the physical laws is the problem of a single observer, who needs for his purpose no collaboration of an obliging assistant sailing through heaven with half the velocity of light. It must be maintained most emphatically that the aspect *B* involves no implication that the different systems obtainable from each other by Lorentzian transformation have anything to do with the actual measures of observers traveling with the corresponding velocity v in relation to the first named system. The quantity v is simply an arbitrary parameter in the equations of transformation, a parameter which does its duty by enabling the transformation to say something about the laws by itself disappearing from the transformed equations. There is no v in the original equations in x, y, z, t , and although v goes into the equations when they are expressed in terms of x', y', z', t' , it mysteriously disappears when everything is boiled down. Even in the case of the electromagnetic equations, where, for example the density ρ in the old equations becomes replaced by $\beta\rho(1 - u_x v/c^2)$, in the transformed equations, u_x being the x component velocity of the electricity in the undashed system, and where v consequently *appears* to take part in the final equations, it actually disappears owing to the fact that the quantity $\beta\rho(1 - u_x v/c^2)$ turns out to be the quantity which, in the dashed system, plays the part of ρ' the electric density in that system.

Having found the forms of the laws in one system of coordinates, the question as to whether or not they are invariant under (1) is a matter to be tested with pen and paper, and not by experiment. *Experiment does play a part in the whole procedure, but its part is played in formulating the laws in one system of coordinates only.*

One immediately commences to wonder what elements are concerned in the question of whether or not *our* system of measures is such that the laws when expressed in terms of them may be expected to be invariant. In order to bring out the essentials of some of the elements here involved, let us consider what the situation would have been if laws had been of such

a type that they were invariant under the Lorentzian transformation when written down in terms of a system of coordinates x, y, z, t , obtainable from ours which we shall call x'', y'', z'', t'' , by the transformation

$$x'' = x - vt; y'' = y; z'' = z; t'' = t \quad (2)$$

i.e., the transformation which a mid-Victorian physicist would have made to allow for what he believed to be a motion of his system of coordinates through space with velocity v . Then, of course, if the laws were written down in the same form but in the double dashed system, they would be wrong. However, if v were of the order of 18 miles per second, which is the sort of velocity we talk about when considering aether drift experiments, it would be necessary to measure to one part in 10^8 , i.e., to an accuracy of v^2/c^2 in order to find the errors in the erroneous laws. Even in our doubled dashed system of coordinates we should consequently discover these laws, although we ought not to. This statement needs some amplification.

If the laws are true when written down in terms of x, y, z, t , i.e., in the system of coordinates which we shall call S , they will also be true when written down in the same form in x', y', z', t' , (the system S') as given by (1), since they are supposed invariant under that transformation. Suppose now, we write them down in the same form, but in x'', y'', z'', t'' , (the system S''). What will be the situation? If we neglect quantities of the order v^2/c^2 , we may write

$$\left. \begin{aligned} x'' &= x'; y'' = y'; z'' = z' \\ t'' &= t' + \frac{v}{c^2}x = t' + \frac{v}{c^2}(x'' + vt'') \\ \text{i.e., } t'' &= t' + \frac{v}{c^2}x'' = t' + \frac{v}{c^2}x' \end{aligned} \right\} \quad (3)$$

Now let there be any experiment which involves the measurement of the differences of the coordinates of two points (denoted by subscripts 1, and 2) which difference remains constant for all values of t' and so of t'' . Such a measurement we shall call a measurement of type I. Then, it is obvious that, excluding the order v^2/c^2 ,

$$x_2'' - x_1'' = x_2' - x_1'; \quad y_2'' - y_1'' = y_2' - y_1'; \quad z_2'' - z_1'' = z_2' - z_1'.$$

Again, suppose that the experiment involves the measurement of the difference between two times at a fixed value of x', y', z' , and hence at a fixed value of x'', y'', z'' . We shall call this a measurement of type II. It is obvious that, in this case, to the order referred to

$$t_2'' - t_1'' = t_2' - t_1'.$$

Now practically all accurate experiments in the field in question involve measurements included in the above types. Thus, suppose for example, we should perform an experiment on the variation of e/m with velocity; and, to fix our ideas, suppose the measurements are made by the usual

magnetic deflection experiment, followed by a compensation of the magnetic deflection by an electrostatic deflection to determine the velocity ω of the electrons. We here use ω to denote the velocity of the electron as distinct from the very much smaller velocity v associated with the transformation. *It is to be distinctly understood that it is the same experiment which is being discussed in the two systems of measures S' and S'' .* The magnetic deflection involves the measurements of lengths which are constant for all time during the experiment, and it also involves the measurement of a magnetic field. The lengths in question involve measurements of the type I, and consequently they are the same excluding the order v^2/c^2 whether they are measured in S' or S'' . As regards the magnetic field, we may trace its measurement according to any consistent scheme, with the same ultimate conclusions. Suppose it is measured by the time of oscillation of a magnet whose moment is subsequently determined by allowing it to vibrate in the vicinity of another similar magnet. The experiment involving the measurement of the time of vibration is one in which two times are recorded at a fixed position, and so is a measurement of type II. The moment of inertia of the magnet involves its dimensions and density. The measurements of the dimensions are of type I. The measurement of density may be regarded as the comparison of the linear dimensions (measurement of type I) of a kilogram of the material, and of the standard kilogram, the equality of the two kilograms being tested by a dynamic method.³ For example, it may be tested by annulment of velocity at impact after traveling with equal and opposite velocities. In this test the velocity as tested in S'' is related to that tested in S' by the relation

$$\frac{dx''}{dt''} = \left(\frac{dx'}{dt'} \right) / 1 + \left(\frac{v}{c^2} \right) \left(\frac{dx'}{dt'} \right)$$

which is easily derivable from (3). In general dx'/dt' would be much less than v , so that $dx''/dt'' = dx'/dt'$ except for quantities of an order less than v^2/c^2 . A similar set of arguments applies to the determination of the moment of the magnet by measuring its time of vibration in the field of a similar magnet, and the net result of all these considerations is that the magnetic field as measured by use of the system of units S' will come out the same as that obtained by using the system S'' , if we neglect v^2/c^2 . A similar conclusion will readily be seen to follow for measurement of the electric field utilized in the determination of ω , the electronic velocity. Hence the net result of all of these considerations is that, exclusive of the order v^2/c^2 , an observer using the system S' will measure values of e/m and of ω which are the same as those obtained by using the system S'' .

It is quite true that the values of ω would be different to a higher order if they could be measured directly in S' and in S'' . For if $x_2' - x_1'$ is the distance travelled by the electron in the time $t_2' - t_1'$ as measured in S' , the velocity ω' as measured in that system is

³ The simple and actually used method of comparison of masses by comparison of weight involves logical complications which would require too much space to unravel here

$$\omega' = \frac{x_2' - x_1'}{t_2' - t_1'}$$

while in S'' , it is

$$\begin{aligned}\omega'' &= \frac{x_2'' - x_1''}{t_2'' - t_1''} = \frac{x_2' - x_1'}{t_2' - t_1' + \frac{v}{c^2}(x_2' - x_1')} \\ &= \frac{x_1' - x_1'}{(t_2' - t_1')\left(1 + \frac{v}{c^2}\omega'\right)}\end{aligned}$$

i. e.,

$$\omega'' = \omega' / \left(1 + \frac{v\omega'}{c^2}\right)$$

which, since ω' may be comparable with c , results in ω'' differing from ω' by quantities of the order $\omega'v/c$. However, it is never in any such way as this that velocities are measured. Even in the measurement of a velocity such as that of light, which approaches most nearly the direct measurement of a velocity, the back and forth journeys of the light are both involved, so that terms involving v/c to the first order become eliminated.

If, in a manner analogous to that adopted above for the e/m experiment we may trace through the kind of experiments whose performance leads to the formulation of the electromagnetic equations, we shall find that if the electromagnetic equations are true when expressed in the measures of S' , the *experiments used to test them* will give the same results in S'' as S' exclusive of the order v^2/c^2 , so that the observer in S'' will discover the equations, although, strictly speaking he ought not to. We must again emphasize that in the above it is the *same* experiments which are supposed discussed in the of S' and S'' units.

It is perhaps worth while pointing out that the electromagnetic equations, when written down in the same form in S' and S'' are not equivalent in all respects up to but excluding v^2/c^2 . Thus if the set expressed in S'' be transformed to S' it will differ from the set originally written down in S' in that in certain places the magnetic fields will have added to them or subtracted from them terms of the order vE/c , and the electric fields will experience corresponding additions or subtractions of the order vH/c . Moreover, terms of the order $\omega'v/c^2$ will make their appearance, where ω' is the velocity of the electricity in S' . All that is maintained is that all experiments so far performed to detect quantities even of the order v/c are experiments falling under classes I and II. This may not seem obvious at first sight in all cases; but if the actual calculations associated with any test be carried completely through to the point where the comparison is between quantities actually measured, it will be found to be true. There are respects in which the electro-

magnetic equations when written down in S' and S'' would differ in their conclusions to the order v/c as regards *ideal* experiments. Thus the wave equation for E is contained in the equations, and in one dimension in free space it is

$$\frac{\partial^2 E'}{\partial t'^2} = c^2 \frac{\partial^2 E'}{\partial x'^2} \quad (4)$$

in S' while, in the same form in S'' it is of course

$$\frac{\partial^2 E''}{\partial t''^2} = c^2 \frac{\partial^2 E''}{\partial x''^2}$$

where E'' refers to the quantity which is defined in S'' in the same manner as E' is defined in S' .

This equation, on transformation to S' by (3) gives

$$\frac{\partial^2 E''}{\partial t'^2} = c^2 \left(\frac{\partial}{\partial x'} - \frac{v}{c^2} \frac{\partial}{\partial t'} \right)^2 E''$$

i.e.,

$$\left(1 - \frac{v^2}{c^2} \right) \frac{\partial^2 E''}{\partial t'^2} = c^2 \left(\frac{\partial^2 E''}{\partial x'^2} - \frac{2v}{c^2} \frac{\partial^2 E''}{\partial x' \partial t'} \right)$$

the general solution of which is

$$E'' = f_1(x' + c_1 t') + f_2(x' - c_2 t')$$

where, excluding terms of the order v^2/c^2

$$c_1 = c - v$$

$$c_2 = c + v$$

and f_1 and f_2 are arbitrary functions. The general solution of (4) is of course

$$E'' = f_1(x' + ct) + f_2(x - ct).$$

Thus, anyone who measured the velocity of a wave directly in the system S' , by measuring the distance travelled by the wave front in one direction in a measured time, would obtain a result differing to the order v/c from that obtained if he had measured the velocity of the same wave in S'' . As already remarked, however, it is not by such procedures that accurate experiments are made.

In view of the foregoing considerations it is not remarkable that we should be led to discover a great scheme of regularity like the electromagnetic scheme lying, as it were, within one part in 10^8 of what our measurements in S'' would predict if we made them with infinite accuracy. Having discovered the scheme of equations, the discovery of its invariance under the Lorentzian transformation is a matter for pen and paper rather than for experiment.

Now, of the two aspects *A* and *B* of the restricted theory of relativity it is *B* which contains the whole of the usefulness of the theory as a working tool. When we study new branches of physics we examine the laws we propose, to see whether they satisfy the mathematical criterion of invariance.⁴ The test, as has been stated, is one of pen and paper, and has no relation whatever to the question of what would happen to measuring apparatus if a velocity were imparted to it.

An example of a class of problem in which, at first sight, we appear to utilize the correspondence between the actual measures and the corresponding Lorentzian system of coordinates, is afforded by the problem leading to the deduction of the Fresnel coefficient on the basis of the theory of relativity. The argument normally proceeds by our taking our stand in imagination in a system of axes moving with the medium. In this system we write for the propagation of a wave along the axis of x ,

$$P = P_0 \sin 2\pi\nu(t - x/V) \quad (5)$$

where V is the velocity applicable to the medium at rest. On applying the Lorentzian transformation to a system S' , specified by (1), equation (5) becomes replaced by

$$P = P_0 \sin 2\pi\nu'(t' - x'/V') \quad (6)$$

where

$$\left. \begin{aligned} \nu' &= \beta\nu(1 - v/V), \quad \beta = (1 - v^2/c^2)^{-1/2} \\ \text{and} \quad V' &= V(1 - v/V)(1 - vV/c^2)^{-1} \end{aligned} \right\} \quad (7)$$

The quantity ν' gives the modification of the original frequency as a result of the Doppler effect, generalized into relativistic form, and V' gives the velocity of the wave in the moving medium when that velocity, which is $-v$ in this case, is measured relative to one who does not participate in the motion of the medium.

The foregoing argument *appears* to involve the principle that if we moved with the medium, the propagation would take place in our frame of reference as it would take place for a medium at rest. The transformation then represents the phenomenon as viewed by one who does not participate in the motion of the medium, and appears to involve something concerned with a relation between the actual measures in the two systems. This conclusion is only apparent, however. The picture of the observer moving along with the medium is one which really plays no part in what we actually do in our mathematical derivation. If we concentrate specifically on what we really do, the story assumes a different aspect as follows: Eq. (5) represents the propagation of the wave with respect to a medium at rest in our axes. We are interested in using the Lorentzian transformation to discover, if possible, the form of the law of propagation when the medium is in motion in our axes. Our criterion is that we must produce a law of propagation which is invariant under the Lorentzian transformation. Now

⁴ I hold no brief for the procedure we adopt, my object here is simply to say what it is.

we may regard our transformation which resulted in (6) as representing the mathematical technique of discovering a suitable invariant law, minus v being the velocity of the medium in our S' system of axes. For we know that a further transformation of the Lorentzian type will leave (6) invariant in form. The equation will, in fact, become

$$P = P_0 \sin 2\pi \bar{v}(\bar{t} - \bar{x}/\bar{V})$$

where

$$\bar{v} = \beta_2 v' (1 - v_2/V'), \quad \beta_2 = (1 - v_2^2/c^2)^{-1/2}$$

$$\bar{V} = V' (1 - v_2/V') (1 - v_2 V'/c^2)^{-1}$$

and v_2 refers to the velocity associated with the second transformation. Remembering that if $-\bar{v}$ the velocity of the medium in the barred system of coordinates, is given by:

$$-\bar{v} = -\frac{v + v_2}{(1 + vv_2/c^2)}$$

and using (7) we readily find that

$$\bar{v} = \bar{\beta}_2 v (1 - \bar{v}/V), \quad \bar{\beta}_2 = (1 - \bar{v}^2/c^2)^{-1/2}$$

$$\bar{V} = V (1 - \bar{v}/V) (1 - \bar{v}V/c^2)^{-1}$$

showing that the second transformation leaves the form (6)–(7) unchanged. The important thing to realize is that the foregoing technique of discovering an invariant law has nothing whatever to do with the question of what would happen in the case of an observer who, with his measuring instrument, participated in the motion of the medium. All that we have said would be applicable if the said measuring instruments were rendered utterly unrelated to their former selves as a result of causing them to move with the medium. There is only *one* set of measuring instruments in mind in the whole argument the set associated with the observer who measures the velocity $-v$ for the medium.

Now the Michelson-Morley-Miller experiment is one sensitive to the order v^2/c^2 ; and a positive result from it invalidates conclusions drawn from the aspect A , but leaves untouched the aspect B , which is the only one of practical use, and which can stand absolutely independent of A .

The aspect B says absolutely nothing about what should happen in the Michelson-Morley-Miller experiment. It has no story to tell as to what happens to things when set in motion, except to this very limited extent: If we knew the complete laws of nature we could predict what happens to a body as a result of changing its motion in any assigned way; and, the aspect B does place upon the complete laws the requirement of invariance. Apart from this, the aspect B is perfectly content if the Michelson-Morley-Miller experiment gives a positive result.

But while one might accept all of the above arguments, he might well say "Yes, but is it not a remarkable thing that the laws of Nature should

be invariant under transformation (1) unless there is something fundamental behind the story?" The old developments of the transformation based upon the postulate of invariance of light velocity, and the relation between the measures of observers in different systems, did place *something* behind the story, even though that something itself did not rest on anything very obvious. The answer to this question is to be found in the general theory of relativity. However, even in this remark we must be careful. It is customary to say that the restricted theory is a special case of the general theory; but, it is only the aspect *B* which is a special case of it. Aspect *A* is not contained in it as a necessary consequence at all. Let us probe the matter a little more deeply.

Perhaps the most concise statement of the general theory applicable to the case in hand is to the effect that it maintains that the laws of nature take the form of differential equations involving the coordinates of things, or quantities expressible in terms of these quantities and involving in addition the derivatives of certain quantities $g_{\mu\nu}$, which satisfy equations usually written

$$G_{\mu\nu} = 0 \quad (8)$$

which are invariant under any point transformation of coordinates, in the sense that if we make an arbitrary transformation, Eq. (8) come back to the same form in new $g_{\mu\nu}$'s which we shall denote by dashed quantities and which are related to the old $g_{\mu\nu}$'s, in such a way as to make

$$\sum \sum g_{\mu\nu} dx_\mu dx_\nu = \sum \sum g_{\mu\nu}' dx_\mu' dx_\nu' \quad (9)$$

ds^2 is usually written for either of the quantities occurring in (9). Moreover, the general theory of relativity demands that the laws of nature shall be invariant under an arbitrary of transformation. An example of such a set of laws is the equation of the geodesic.

$$\frac{d^2 x_\mu}{ds^2} + \frac{1}{2} \sum_{\alpha=1}^4 \sum_{\nu=1}^4 \sum_{\lambda=1}^4 \left\{ g^{\mu\lambda} \left(\frac{\partial g_{\alpha\lambda}}{\partial x_\nu} + \frac{\partial g_{\nu\lambda}}{\partial x_\alpha} - \frac{\partial g_{\alpha\nu}}{\partial x_\lambda} \right) \right\} \frac{dx_\alpha}{ds} \frac{dx_\nu}{ds} = 0 \quad (10)$$

where $g^{\mu\lambda} = \frac{\text{minor of } g_{\mu\lambda}}{g}$, and $g = \begin{vmatrix} g_{11} & g_{12} & g_{13} & g_{14} \\ g_{41} & g_{42} & g_{43} & g_{44} \end{vmatrix}$.

In the first place, I would remark that the invariance as understood in (10) is a very different kind of thing from the invariance as understood in the restricted theory. If in (10), the derivatives of the g 's were inserted as functions of the coordinates, the resulting equation would not be invariant under any transformation of coordinates. It is not as invariant as all that. It would not, in general, be invariant even under the Lorentzian transformation. By the invariance of (10) we mean⁵ that on an arbitrary transformation it comes back to the same form in new g 's which are related to the old g 's by (9).

⁵ A fuller discussion of the significance of invariance in the general theory will be given in a paper "Relativity and Electrodynamics" now in process of publication in the Physical Review Supplement.

Now if there is a region of space in which the g 's become

$$\left. \begin{aligned} g_{\mu\nu} &= 0 \quad \text{if } \mu \neq \nu \\ g_{11} &= g_{22} = g_{33} = -g_{44}/c^2 = -1 \end{aligned} \right\} \quad (11)$$

so that, using x, y, z, t , instead of x_1, x_2, x_3, x_4

$$ds^2 = -dx^2 - dy^2 - dz^2 + c^2 dt^2 \quad (12)$$

then, since it is a characteristic of the Lorentzian transformation that it leaves (12) invariant, i.e. that it leaves the new g 's as $-1, -1, -1, c^2$ if the old g 's were $-1, -1, -1, c^2$, we see that in a region where the g 's are of the form (11) such equations as (10) or, of course, any other equations invariant in the sense of the general theory will be invariant not only in that sense but in the more drastic sense of the restricted theory for the Lorentzian transformation. For the form (11), which makes all the g 's constants, requires all the terms involving g 's to vanish in the system of coordinates in which (11) holds, and consequently the invariance of (12) under the Lorentzian transformation insures the disappearance of the g 's from equations (10) when expressed in any system of coordinates derivable from the former set by a Lorentzian transformation. We may then say that if in any set of laws we have g 's such functions of the coordinates that the ds^2 as given by

$$ds^2 = \sum g_{\mu\nu} dx_\mu dx_\nu$$

reverts at infinity to (12), or to something transformable to that form; then, when expressed in terms of the coordinates applicable to the form (12) the special theory will hold in the form B . This is perhaps the most logical birth-place of the special theory. The special theory will not hold however, in a system of coordinates derivable from one of the Lorentzian set by a transformation which is not a Lorentzian transformation. To illustrate the matter let us consider the problem of astronomical motion, in which it is customary to take such solutions of (8) as give a line element of the symmetrical form:

$$ds^2 = -\gamma^{-1} dr^2 - r^2 d\theta^2 - r^2 \sin^2 \theta d\phi^2 + c^2 \gamma dt^2 \quad (13)$$

where

$$\gamma = 1 - 2m/r.$$

If we go off to infinity, γ becomes unity, and the line element assumes the ordinary polar form transformable to the form

$$ds^2 = -dx^2 - dy^2 - dz^2 + c^2 dt^2 \quad (14)$$

by the ordinary transformation for polar coordinates. We should therefore conclude that in the coordinates x, y, z, t , occurring in (14) the special theory should hold for all differential equations to which the g 's of (13) were in the more general case applicable.

Suppose however, that taking (13) and before proceeding to infinity we make a single transformation equivalent in Cartesian coordinates to

$$x'' = x + vt, \quad y'' = y; \quad z'' = z, \quad t'' = t. \quad (15)$$

The new g 's appropriate to the new expression of the line element would be solutions of (8), for no transformation would rob them of this property since (8) is invariant under any transformation. In proceeding to the solution of any problem in these coordinates, we should, of course, obtain exactly the same differential equations as we obtained before⁶ but transformed to the dashed system of coordinates specified by (15). We should obtain exactly the result which would be obtained by a mid-Victorian physicist who had somehow or other been led to the differential equations which he considered as applicable to the subject when referred to axes at rest and had then corrected them because he learned that the solar system was moving through space with a velocity v . When we proceed to infinity, however, with our x'' , y'' , z'' , t'' , coordinates, we no longer obtain a line element of the form (14) but one obtainable from it by the transformation (15); and the form of this line element tells us immediately that the restricted theory even in the aspect B will not hold in the coordinates in terms of which that line element is expressed.

Thus, all that the general theory predicts as regards the restricted theory, is that, if we make a transformation back from x'' , y'' , z'' , t'' , to x , y , z , t , we shall find ourselves in a set of coordinates such that at infinity the laws expressed in terms of them will be invariant under the Lorentzian transformation, so that they will also be invariant in any coordinates obtained from these coordinates by a Lorentzian transformation. They will not, however, be invariant when expressed in the double dashed coordinates. Further, the general theory, at least without further hypothesis, has no story to tell as to the relation between different Lorentzian systems of coordinates and the corresponding measuring rods, etc. I am perfectly aware of the fact that the equivalence of the line element ds and the ds of experimental measurements is frequently stressed. I merely wish to point out that such equivalence amounts to an extra postulate, and a postulate not essential to the main content of the general or restricted theories—a postulate moreover which leads to such dangerous conclusions as are involved in the “red shift” of the spectrum lines of the sun, and which appears to place upon the theory a burden of prediction greater than it need bear.

⁶ We here refer to the differential equations typified in the astronomical problem by the equations obtained from (10) by substituting the appropriate values of the g 's.

THE SPATIAL DISTRIBUTION OF PHOTOELECTRONS

BY S. E. SZCZENIOWSKI*

RYERSON PHYSICAL LABORATORY, UNIVERSITY OF CHICAGO

(Received December 6, 1929)

ABSTRACT

The perturbation of a hydrogen-like atom by a plane polarized electromagnetic wave is considered on the basis of Dirac's equation, and perturbed wave functions are obtained. These functions lead by a method similar to that used by Sommerfeld in his "Wellenmechanisches Ergänzungsband" to a formula for the spatial distribution of the photoelectrons. To the first approximation this formula differs from that given by a factor 5/9 in the second term. The angle between the average direction of the emission of the photoelectrons and the electric vector of the incident wave appears therefore to be equal to $h\nu/cmv$ instead of the value $(9/5)(h\nu/cmv)$ given. The factor 5/9 follows from the consideration of the normalizing factors for the spherical harmonics, which were not introduced by Sommerfeld. A second approximation has also been obtained showing the influence of electron spin. This approximation differs from that obtained by Carrelli in that the spin and some other terms not considered by Carrelli and also the factor 5/9 appear.

THE photoelectric effect has been treated theoretically on the basis of the wave mechanics by G. Wentzel,¹ G. Beck² and by A. Sommerfeld,³ who gave a better approximation than the first two authors. However, all these authors have started either from the ordinary form of the Schrödinger equation (Wentzel, Beck) or from the form which takes into account the magnetic field but does not consider the relativity and spin effects. It is therefore of some interest to make the corresponding calculations on the basis of the wave equation given by Dirac. By means of this equation the relativity corrections and the spin influence can be found.

The computations in the present paper will proceed in a manner closely similar to the one used by Sommerfeld in his book.

I. PERTURBATION OF A HYDROGEN-LIKE ATOM BY AN ELECTROMAGNETIC WAVE

Dirac has shown⁴ that the Hamiltonian expression for one electron can be written in the form

$$H = (p_0 + eA_0/c) + \rho_1(\sigma, p + eA/c) + \rho_3 mc. \quad (1)$$

In this expression ρ_1, ρ_3 are four-row matrices, σ is a vector four-row matrix, whose components $\sigma_1, \sigma_2, \sigma_3$ are ordinary four-row matrices which satisfy the following relations

* Fellow of the International Education Board.

¹ G. Wentzel, *Zeits. f. Physik* **40**, 574 (1926); **41**, 828 (1926).

² G. Beck, *Zeits. f. Physik* **41**, 443 (1927).

³ A. Sommerfeld, *Atombau und Spektrallinien*, *Wellenmechanisches Ergänzungsband*, p. 207.

⁴ P. A. M. Dirac, *Proc. Roy. Soc. A* **117**, 610 (1928); **118**, 351 (1928).

$$\begin{aligned}\sigma_1\sigma_2 &= i\sigma_3 = -\sigma_2\sigma_1 \\ \sigma_2\sigma_3 &= i\sigma_1 = -\sigma_3\sigma_2\end{aligned}\quad (2)$$

$$\begin{aligned}\sigma_3\sigma_1 &= i\sigma_2 = -\sigma_1\sigma_3 \\ \sigma_1^2 &= 1; \quad \sigma_2^2 = 1; \quad \sigma_3^2 = 1.\end{aligned}\quad (3)$$

Similar relations are valid for ρ_1, ρ_3 ; moreover all σ 's are commutable with all ρ 's.

The parenthesis $(\sigma, p + eA/c)$ stands for a scalar product of the two vectors σ and $p + eA/c$. A is the vector potential, A_0 the scalar potential.

To the Hamiltonian (1) correspond two mutually adjoint functions, ψ and ϕ , each of which has four components.

To obtain Dirac's equations it is to be assumed that

$$p_0 = \frac{i\hbar}{2\pi c} \frac{\partial}{\partial t} \quad (4)$$

and p is to be interpreted as a vector operator, whose components are given by the relations

$$p_x = -\frac{i\hbar}{2\pi} \frac{\partial}{\partial x}; \quad p_y = -\frac{i\hbar}{2\pi} \frac{\partial}{\partial y}; \quad p_z = -\frac{i\hbar}{2\pi} \frac{\partial}{\partial z}. \quad (5)$$

Then simultaneously

$$(p_0 + eA_0/c)\psi + \rho_1(\sigma, p + eA/c)\psi + \rho_3 mc\psi = 0 \quad (6)$$

$$\phi(-p_0 + eA_0/c) + \phi\rho_1(\sigma, -p + eA/c) + \phi\rho_3 mc = 0. \quad (7)$$

In the Eqs. (6) and (7) the following notation has been used. If μ is a four rowed matrix, then

$$\mu\psi = \sum_{k=1}^4 \mu_{ik}\psi_k \quad (i=1,2,3,4) \quad (8)$$

$$\phi\mu = \sum_{k=1}^4 \phi_k\mu_{ki} \quad (i=1,2,3,4) \quad (9)$$

If the matrices ρ and σ are hermitian, as, for instance, those given by Dirac,⁴ ϕ is the conjugate complex function to ψ . This will be the case in the present paper. The operators p_0 and p in Eq. (7) operate backwards.

Dirac has shown, also, that the electric charge and current densities are given by

$$\rho = -e\varphi\psi \quad (10)$$

and

$$J = ec\phi\rho_1\sigma\psi. \quad (11)$$

In these expressions $\phi\psi$ stands for $\sum_{k=1}^4 \phi_k\psi_k$ and $\phi\mu\psi$ for $\sum_{i,k=1}^4 \phi_i\mu_{ik}\psi_k$.

It will be convenient to use the equations of second order, which correspond to the Eqs. (6) and (7) and in the present case will be equivalent to

them. These equations were also derived by Dirac and can be written in the form

$$\left\{ -\left(\frac{i\hbar}{2\pi c} \frac{\partial}{\partial t} + \frac{eV}{c} \right)^2 + \left(-\frac{i\hbar}{2\pi} \nabla + \frac{eA}{c} \right)^2 + m^2 c^2 \right\} \psi + \frac{e\hbar}{2\pi c} (\sigma, H) \psi + \frac{ie\hbar}{2\pi c} \rho_1 (\sigma, E) \psi = 0 \quad (12)$$

$$\left\{ -\left(-\frac{i\hbar}{2\pi c} \frac{\partial}{\partial t} + \frac{eV}{c} \right)^2 + \left(\frac{i\hbar}{2\pi} \nabla + \frac{eA}{c} \right)^2 + m^2 c^2 \right\} \phi + \frac{e\hbar\phi}{2\pi c} (\sigma, H) - \frac{ie\hbar}{2\pi c} \phi \rho_1 (\sigma, E) = 0 \quad (13)$$

In these equations ∇ stands for a vector operator with components $\partial/\partial x$, $\partial/\partial y$, $\partial/\partial z$; H and E are the magnetic and electric field intensities which correspond to the scalar potential $V=A_0$ and the vector potential A , whereas (σ, H) and (σ, E) are scalar products of vectors σ and H or σ and E respectively.

The point of departure for the following considerations will be an undisturbed hydrogen-like atom in the k -th quantum state, consequently V will be equal to Ze/r , where Ze is the charge of the nucleus. The corresponding initial proper functions will be denoted by ψ_k and ϕ_k . As in the present case ϕ_k is always the conjugate complex function to ψ_k it will be sufficient to consider only the functions ψ .

Accordingly the initial conditions are described by the equations

$$\left\{ -\left(\frac{i\hbar}{2\pi c} \frac{\partial}{\partial t} + \frac{eV}{c} \right)^2 + \left(-\frac{i\hbar}{2\pi} \nabla \right)^2 + m^2 c^2 \right\} \psi_k + \frac{ie\hbar}{2\pi c} \rho_1 (\sigma, E_0) \psi_k = 0 \quad (14)$$

where E_0 designates the intensity of the electrostatic field of the nucleus.

Eq. (14) can be written in the form

$$\frac{1}{c^2} \frac{\partial^2 \psi_k}{\partial t^2} - \Delta \psi_k - \frac{4\pi ieV}{\hbar c^2} \frac{\partial \psi_k}{\partial t} - \frac{4\pi^2 e^2 V^2}{\hbar^2 c^2} \psi_k + \frac{4\pi^2 m^2 c^2}{\hbar^2} \psi_k + \frac{2\pi ie}{\hbar c} \rho_1 (\sigma, E_0) \psi_k = 0 \quad (15)$$

It will be now supposed that the atom is disturbed by a plane polarized electromagnetic wave, whose field can be derived from the vector potential

$$A = A_x = a \cos 2\pi\nu \left(t - \frac{z}{c} \right)$$

It is known that

$$H = \text{curl } A ; \quad E = -\text{grad } A_0 - \dot{A}/c \quad (16)$$

and therefore

$$\begin{aligned} H_x = H_z = 0 ; \quad H_y &= a \cdot (2\pi\nu/c) \sin 2\pi\nu(t - z/c) \\ E_y = E_z = 0 ; \quad E_x &= a \cdot (2\pi\nu/c) \sin 2\pi\nu(t - z/c). \end{aligned} \quad (17)$$

Eqs. (17) correspond to an electromagnetic wave, which proceeds in the direction of the z axis and is polarized in the yz plane.

If the values (17) are applied to Eq. (12) it assumes the form

$$\begin{aligned} & \frac{1}{c^2} \frac{\partial^2 \psi}{\partial t^2} - \frac{4\pi^2 e^2 V^2}{h^2 c^2} \psi - \frac{4\pi i e V}{h c^2} \frac{\partial \psi}{\partial t} - \Delta \psi - \frac{4\pi i e a}{h c} \cos 2\pi \nu \left(t - \frac{z}{c} \right) \frac{\partial \psi}{\partial x} \\ & + \frac{4\pi^2 e^2 a^2}{h^2 c^2} \psi \cos^2 2\pi \nu \left(t - \frac{z}{c} \right) + \frac{4\pi^2 m^2 c^2}{h^2} \psi + \frac{4\pi^2 \nu e a}{h c^2} \sin 2\pi \nu \left(t - \frac{z}{c} \right) \sigma_2 \psi \\ & + \frac{2\pi i e}{h c} \rho_1(\sigma, E_0) \psi + \frac{4\pi^2 i e a \nu}{h c^2} \rho_1 \sigma_1 \psi \sin 2\pi \nu \left(t - \frac{z}{c} \right) = 0. \end{aligned} \quad (18)$$

It is convenient to introduce exponentials instead of sines and cosines in Eq. (18). Moreover the term with a^2 as a factor can be neglected, since usually the amplitude a of the disturbing wave is very small. Then

$$\begin{aligned} & \frac{1}{c^2} \frac{\partial^2 \psi}{\partial t^2} - \frac{4\pi^2 e^2 V^2}{h^2 c^2} \psi - \frac{4\pi i e V}{h c^2} \frac{\partial \psi}{\partial t} - \Delta \psi + \frac{4\pi^2 m^2 c^2}{h^2} \psi + \frac{2\pi i e}{h c} \rho_1(\sigma, E_0) \psi \\ & - \frac{2\pi i e a}{h c} \frac{\partial \psi}{\partial x} [e^{2\pi i \nu(t-z/c)} + e^{-2\pi i \nu(t-z/c)}] - \frac{2\pi^2 i e a}{h c^2} [e^{2\pi i \nu(t-z/c)} \\ & - e^{-2\pi i \nu(t-z/c)}] \sigma_2 \psi + \frac{2\pi^2 e \nu a}{h c^2} [e^{2\pi i \nu(t-z/c)} - e^{-2\pi i \nu(t-z/c)}] \rho_1 \sigma_1 \psi = 0. \end{aligned} \quad (19)$$

Eq. (19) can be simplified by the introduction of a perturbation parameter $\chi = -2\pi i e a / h c$. On account of the factor a this parameter is a small quantity, so that all the terms, which have a power of a larger than unity as a factor can be neglected. Therefore it can be assumed that

$$\psi = \psi_k + \chi v + \dots \quad (20)$$

In the expression above ψ_k denotes the proper function for the initial state of the atom and therefore

$$\psi_k = \bar{\psi}_k e^{-2\pi i E_k t / h} \quad (21)$$

where E_k is the proper energy of the atom in the initial state and $\bar{\psi}_k$ is a function of the spatial coordinates only. On account of Eq. (20) the substitution of (21) into Eq. (19) leads to

$$\begin{aligned} & \frac{1}{c^2} \frac{\partial^2 v}{\partial t^2} - \frac{4\pi^2 e^2 V^2}{h^2 c^2} v - \frac{4\pi i e V}{h c^2} \frac{\partial v}{\partial t} - \Delta v + \frac{4\pi^2 m^2 c^2}{h^2} v + \frac{2\pi i e}{h c} \rho_1(\sigma, E_0) v \\ & + \frac{\partial \bar{\psi}_k}{\partial x} \left\{ \exp \left[-\frac{2\pi i}{h} (E_k + h\nu) t + 2\pi i \nu \frac{z}{c} \right] \right. \\ & + \exp \left[-\frac{2\pi i}{h} (E_k - h\nu) t - 2\pi i \nu \frac{z}{c} \right] \left. \right\} \\ & + \frac{\pi \nu}{c} \left\{ \exp \left[-\frac{2\pi i}{h} (E_k - h\nu) t - 2\pi i \nu \frac{z}{c} \right] \right. \end{aligned} \quad (22)$$

$$\begin{aligned}
& -\exp\left[-\frac{2\pi i}{h}(E_k+h\nu)t+2\pi i\nu\frac{z}{c}\right]\bigg\}\sigma_2\psi \\
& +\frac{i\pi\nu}{c}\bigg\{\exp\left[-\frac{2\pi i}{h}(E_k-h\nu)t-2\pi i\nu\frac{z}{c}\right] \\
& -\exp\left[-\frac{2\pi i}{h}(E_k+h\nu)t+2\pi i\nu\frac{z}{c}\right]\bigg\}\rho_1\sigma_1\bar{\psi}=0
\end{aligned}$$

The terms with the squares of χ were omitted, according to the former assumption.

The form of Eq. (22) suggests that

$$v=v_+e^{-(2\pi i/h)(E_k+h\nu)t}+v_-e^{-(2\pi i/h)(E_k-h\nu)t}. \quad (23)$$

If z/λ is written instead of $\nu z/c$ then, on account of (23) Eq. (22) takes the form

$$\begin{aligned}
& -\frac{4\pi^2}{h^2c^2}(E_k\pm h\nu)^2v_{\pm}-\frac{4\pi^2e^2V^2}{h^2c^2}v_{\pm}-\frac{8\pi^2eV}{h^2c^2}(E_k\pm h\nu)v_{\pm}-\Delta v_{\pm} \\
& +\frac{4\pi^2m^2c^2}{h^2}v_{\pm}+\frac{2\pi ie}{hc}\rho_1(\sigma, E_0)v_{\pm}+\frac{\partial\bar{\psi}_k}{\partial x}e^{\pm 2\pi iz/\lambda} \\
& \mp\frac{\pi\nu}{c}e^{\pm 2\pi iz/\lambda}\sigma_2\bar{\psi}_k\mp\frac{i\pi\nu}{c}e^{\pm 2\pi iz/\lambda}\rho_1\sigma_1\bar{\psi}_k=0.
\end{aligned} \quad (24)$$

All upper signs in this equation belong together; the same applies to the lower signs.

Eq. (24) can be written in the form

$$\begin{aligned}
\Delta v_{\pm}+\frac{4\pi^2}{h^2c^2}[(E_k\pm h\nu+eV)^2-m^2c^4]v_{\pm}-\frac{2\pi ie}{hc}\rho_1(\sigma, E_0)v_{\pm} \\
=\frac{\partial\bar{\psi}_k}{\partial x}e^{\pm 2\pi iz/\lambda}\mp\frac{\pi}{\lambda}e^{\pm 2\pi iz/\lambda}\sigma_2\bar{\psi}_k\mp\frac{i\pi}{\lambda}e^{\pm 2\pi iz/\lambda}\rho_1\sigma_1\bar{\psi}_k.
\end{aligned} \quad (25)$$

Since

$$(E_k\pm h\nu+eV)^2-m^2c^4=(E_k\pm h\nu+eV+mc^2)(E_k\mp h\nu+eV-mc^2) \quad (26)$$

and, except for very great values of ν , the expression $E_k\pm h\nu+eV$ is nearly equal to mc^2 , it follows that the Eq. (25) differs from that given by Sommerfeld⁵ only by the terms connected with the electron spin.

However, it is to be remembered that in Eq. (25) the functions v_+ and v_- stand for four components each. Furthermore in Sommerfeld's equations e is the electron charge, whereas in the present paper e denotes the absolute value of the electron charge. This explains the difference of signs, since eV stands for Sommerfeld's $-U$.

The solution of the Eq. (25) can be assumed in the form of an infinite series of the proper solutions of the undisturbed problem. However it is to

⁵ A. Sommerfeld, reference 3, p. 195, Eq. (8).

be taken into account, that the hydrogen atom has a continuum of proper functions for electron energies greater than mc^2 in addition to a discrete set of proper functions for electron energies less than mc^2 . Accordingly

$$v_{\pm} = \sum_i B_i^{\pm} \bar{\psi}_i + \int B^{\pm}(E') \bar{\psi}(E') dE'. \quad (27)$$

However, the expansion of the right side of the Eq. (25) into a corresponding series of proper functions meets a difficulty pointed out by Darwin.⁶ Darwin has shown that the proper functions of the hydrogen atom form an incomplete set of orthogonal functions and that therefore it is not possible to develop an arbitrary four component function into a series of these proper functions. To do this the number of orthogonal solutions must be doubled. It means that in order to go through the calculations the existence of the solutions which correspond to the negative proper energies of the electron must be admitted. These solutions are obtained if the sign of the electron charge in Dirac's equation is changed from negative to positive and it is clear that they have no physical meaning. Therefore it is to be remembered that only those terms of the above mentioned series expansion which correspond to positive proper energies are to be taken into account in further considerations.

According to these considerations the series expansion can be written in the following form

$$\begin{aligned} \frac{\partial \bar{\psi}_k}{\partial x} e^{\pm 2\pi i z/\lambda} \mp \frac{\pi}{\lambda} e^{\pm 2\pi i z/\lambda} \sigma_2 \bar{\psi}_k \mp \frac{i\pi}{\lambda} e^{\pm 2\pi i z/\lambda} \rho_1 \sigma_1 \bar{\psi}_k \\ = \sum_i A_i^{\pm} \bar{\psi}_i + \int A^{\pm}(E') \bar{\psi}(E') dE'. \end{aligned} \quad (28)$$

The integrals in the equation above are to be extended from $E' = mc^2$ to $E' \rightarrow \infty$ and from $E' = -mc^2$ to $E' \rightarrow -\infty$, but only the integrals within positive limits have a physical meaning.

The functions $\bar{\psi}_i, \bar{\psi}(E')$ are solutions of the undisturbed Eq. (14) and therefore

$$\begin{aligned} -\frac{4\pi^2}{h^2 c^2} E_i^2 \bar{\psi}_i - \Delta \bar{\psi}_i - \frac{8\pi^2}{h^2 c^2} E_i eV \bar{\psi}_i - \frac{4\pi^2 e^2 V^2}{h^2 c^2} \bar{\psi}_i \\ + \frac{4\pi^2 m^2 c^2}{h^2} \bar{\psi}_i + \frac{2\pi i e}{hc} \rho_1(\sigma, E_0) \bar{\psi}_i = 0. \end{aligned} \quad (29)$$

Similar equation is valid for $\bar{\psi}(E')$

The Eq. (29) leads to

$$\Delta \bar{\psi}_i - \frac{2\pi i e}{hc} \rho_1(\sigma, E_0) \bar{\psi}_i = -\frac{4\pi^2}{h^2 c^2} [(E_i + eV)^2 - m^2 c^4] \bar{\psi}_i. \quad (30)$$

⁶ G. Darwin, Proc. Roy. Soc. A118, 654 (1928).

If Eqs. (27), (28) and (30) are substituted into (26), then it is found that

$$B_j^\pm = \frac{h^2 c^2}{4\pi^2} \frac{A_j^\pm}{(E_k \pm h\nu + eV)^2 - m^2 c^4} \quad (31)$$

$$B^\pm(E') = \frac{h^2 c^2}{4\pi^2} \frac{A^\pm(E')}{(E_k \pm h\nu + eV)^2 - (E' + eV)^2}.$$

On account of these relations Eqs. (20) leads to

$$\begin{aligned} \psi = & \bar{\psi}_k e^{-2\pi i E_k t / h} - \frac{h c i e a}{2\pi} \left\{ \left[\sum_j \frac{A_j^+ \bar{\psi}_j}{(E_k + h\nu + eV)^2 - (E_j + eV)^2} \right. \right. \\ & + \left. \int \frac{A^+(E') \bar{\psi}(E') dE'}{(E_k + h\nu + eV)^2 - (E' + eV)^2} \right] e^{-2\pi i (E_k + h\nu) t / h} \\ & + \left[\sum_j \frac{A_j^- \bar{\psi}_j}{(E_k - h\nu + eV)^2 - (E_j + eV)^2} \right. \\ & + \left. \left. \int \frac{A^-(E') \bar{\psi}(E') dE'}{(E_k - h\nu + eV)^2 - (E' + eV)^2} \right] e^{-2\pi i (E_k - h\nu) t / h} \right\}. \end{aligned} \quad (32)$$

From Eq. (10) the electric charge density is

$$\begin{aligned} \rho = & -e \bar{\phi}_k \bar{\psi}_k + \frac{h c i e a}{2\pi} \left\{ e^{2\pi i \nu t} \left[\sum_j \frac{A_j^+ \bar{\phi}_j \bar{\psi}_k}{(E_k + h\nu + eV)^2 - (E_j + eV)^2} \right. \right. \\ & - \sum_j \frac{A_j^- \bar{\phi}_j \bar{\psi}_k}{(E_k - h\nu + eV)^2 - (E_j + eV)^2} \left. \right] + e^{-2\pi i \nu t} \left[\sum_j \frac{A_j^+ \bar{\phi}_j \bar{\psi}_k}{(E_k + h\nu + eV)^2 - (E_j + eV)^2} \right. \\ & - \sum_j \frac{A_j^- \bar{\phi}_j \bar{\psi}_k}{(E_k - h\nu + eV)^2 - (E_j + eV)^2} \left. \right] \left. \right\}. \end{aligned} \quad (33)$$

According to the former assumptions the terms whose coefficients are proportional to a^2 were neglected, furthermore the integrals, which correspond to the continuous spectrum are not written out.

From Eq. (33), which is very similar to the one given by Sommerfeld⁷ the dispersion formulas could be obtained in the usual way.

As long as $h\nu \ll mc^2$

$$(E_k \pm h\nu + eV)^2 - (E_j + eV)^2 \cong 2mc^2(E_k - E_j \pm h\nu) \quad (34)$$

because the energy values include the energy mc^2 , so that on the one hand eV is negligibly small with regard to E_k or E_j (except for the K -levels of the heavy elements) and on the other hand each of these terms differs only negligibly (with the same exception) from mc^2 (the energy mc^2 in electron-volts is of the order of $5 \cdot 10^5$).

With that simplification the Eq. (33) leads to the usual dispersion formula. Only when $h\nu$ begins to be comparable with mc^2 and especially for the

⁷ A. Sommerfeld, reference 3, p. 197.

heaviest elements does Eq. (33) give results differing appreciably from the usual dispersion formula. As $h\nu$ is equal to mc^2 for $\lambda \cong 24XU$ it follows that the difference begins to be appreciable for X-rays of the order of 0.1A.

According to Eq. (28) the value of A_j^\pm is given by

$$A_j^\pm = \frac{1}{C_j} \left\{ \int \bar{\phi}_j \frac{\partial \bar{\psi}_k}{\partial x} e^{\pm 2\pi i z/\lambda} d\tau \mp \frac{\pi}{\lambda} \int e^{\pm 2\pi i z/\lambda} \bar{\phi}_j \sigma_2 \bar{\psi}_k d\tau \right. \\ \left. \mp \frac{i\pi}{\lambda} \int e^{\pm 2\pi i z/\lambda} \bar{\phi}_j \rho_1 \sigma_1 \bar{\psi}_k d\tau \right\}. \quad (35)$$

Eq. (35) is obtained if Eq. (28) is multiplied by $\bar{\phi}_j$ on the left-hand side and integrated over the whole space. Furthermore the normalizing integrals

$$\int \bar{\phi}_j \bar{\psi}_j d\tau = C_j \quad (36)$$

are to be used. The integrations in the expressions (36) extend over the whole space.

II. THE PHOTOELECTRIC CURRENT

The photoelectric current excited in a given direction by an electromagnetic wave incident on a hydrogen like atom can now be found on the basis of Eq. (32). Only the photoelectric emission from a single atom will be considered here. To calculate this emission, those excited states of the atom which belong to the continuous spectrum are to be considered. Therefore in the present case the sums in Eq. (32) can be omitted as irrelevant. The values of the coefficients $A^\pm(E')$ are given by the formulas

$$A^\pm(E') = \frac{1}{C(E')} \left\{ \int \bar{\phi}(E') \frac{\partial \bar{\psi}_k}{\partial x} e^{\pm 2\pi i z/\lambda} d\tau \mp \frac{\pi}{\lambda} \int \bar{\phi}(E') \sigma_2 \bar{\psi}_k e^{\pm 2\pi i z/\lambda} d\tau \right. \\ \left. \mp \frac{i\pi}{\lambda} \int \bar{\phi}(E') \rho_1 \sigma_1 \bar{\psi}_k e^{\pm 2\pi i z/\lambda} d\tau \right\} \quad (37)$$

where

$$C(E') = \lim_{\Delta_n E' \rightarrow 0} \frac{\int \Delta_n \bar{\phi}(E') \Delta_n \bar{\psi}(E') d\tau}{\Delta_n E'} \quad (38)$$

(the integral extends over the whole space) and

$$\Delta_n \bar{\phi}(E') = \int_{\Delta_n E} \bar{\phi}(E') dE'; \quad \Delta_n \bar{\psi}(E') = \int_{\Delta_n E} \bar{\psi}(E') dE' \quad (39)$$

(see Fuess⁸).

In Eq. (32) the term $\bar{\psi}_k e^{-2\pi i E_k t/\hbar}$ can be also omitted. This term represents the initial k -th quantum state of the atom and therefore its radial part contains an exponential of the type $e^{-\mu r}$, where μ is a real positive number.

⁸ E. Fuess, Ann. d. Physik 81, 281 (1926).

Since $\mu \sim 10^9$ this exponential vanishes very rapidly with increasing r . (The same applies to the terms of the sums in Eq. (32)). On the other hand the radial parts of the functions $\bar{\varphi}(E')$ have as a factor an exponential $e^{\mu' r}$ where μ' is purely imaginary. They vanish therefore only slowly with growing r . It follows that for the values of r great compared with the atomic dimensions (and it is these values that are to be considered for the photoelectric effect) only the integrals in Eq. (32) are to be taken into account.

According to Sommerfeld⁹ the integrands of these integrals can be separated into three factors

$$a) \frac{A^{\pm}(E')}{(E_k \pm h\nu + eV)^2 - (E' + eV)^2}; \quad b) \bar{\psi}(E') \quad \text{and} \quad c) e^{-2\pi i(E_k \pm h\nu)t/\hbar}.$$

In the factor (a) only V depends upon the coordinates, but, as V is equal to eZ/r it can be safely omitted in the computations. The factor (a) then becomes a constant, i.e. it depends only upon E' .

The factor (c) gives the dependence of $\bar{\psi}$ upon the time. The expression $E_k \pm h\nu$ in the exponent can be interpreted as the energy of the photoelectron. The kinetic energy of the photoelectron is

$$\epsilon = E_k \pm h\nu - mc^2.$$

If the $+$ sign is taken this can be written in the form $\epsilon = h\nu - J$ where $J = mc^2 - E_k$ is the ionization potential. The corresponding expression with the $-$ sign becomes negative. Hence there cannot be given a physical interpretation to the corresponding parts of ψ unless the possibility of existence of states with negative total energy is admitted. The existence of these states has already been admitted to obtain an expansion of the right side of the perturbed Eq. (25) into a series of the proper functions of the undisturbed problem. The factor $E_k - h\nu$ could then be written in the form $-(-E_k + h\nu)$ and the negative kinetic energy of the photoelectron, which evidently has no physical significance would be $\epsilon' = -(-E_k + h\nu) - (-mc^2)$ or $\epsilon' = -(h\nu - J)$. This forms an analogue to Einstein's photoelectric equation.

According to the above considerations these parts of ϕ which correspond to the $-$ sign in the expression $E_k \pm h\nu$ can be omitted, the more so, that the parts with the $+$ sign will be incomparably greater than the parts with the $-$ sign on account of the expression $(E_k + h\nu + eV)^2 - (E' + eV)^2$ in the denominator of the integrands, which tends to zero with E' tending to $E_k + h\nu$.

The factor (b) is the really interesting one for the determination of the spatial distribution of the photoelectrons. Moreover it must be added that only the radial parts of the functions ψ have the continuous spectra. The directional parts have only the discrete proper functions. Therefore on account of the foregoing considerations the following expressions are properly to be used in the subsequent calculations (because A_j^{\pm} and $A(\pm E')$ should be explicitly written as A_{jkm}^{\pm} and $A_{km}^{\pm}(E')$)

⁹ A. Sommerfeld, reference 3, p. 209.

$$\psi \cong -\frac{hc\epsilon_0 e a}{2\pi} e^{-2\pi i(E_{k_0} + h\nu)t/\hbar} \left\{ \sum_k \sum_m \int \frac{A_{km}^+(E') \bar{\psi}_{km}(E') dE'}{(E_{k_0} + h\nu + eV)^2 - (E' + eV)^2} \right\}. \quad (40)$$

To avoid the divergence of the integral in (40) the integration can be performed according to Wentzel¹⁰ along a path which extends slightly around the pole $E' = E_{k_0} + h\nu$ into the positive part of the complex plane E' .

Darwin¹¹ has shown that the solutions of Dirac's equations for a central electrostatic field can be written in the form

$$\begin{aligned} \bar{\psi}_{km}^{(1)} &= -iF_k P_{k+1}^m & \bar{\psi}_{km}^{(3)} &= (k+m+1)G_k P_k^{m+1} \\ \bar{\psi}_{km}^{(2)} &= -iF_k P_{k+1}^{m-1} & \bar{\psi}_{km}^{(4)} &= (-k+m)G_k P_k^{m+1} \end{aligned} \quad (41)$$

and

$$\begin{aligned} \bar{\psi}_{km}^{(1)} &= -i(k+m)F_{-k-1} P_{k-1}^m & \bar{\psi}_{km}^{(3)} &= G_{-k-1} P_k^m \\ \bar{\psi}_{km}^{(2)} &= -i(-k+m+1)F_{-k-1} P_{k-1}^{m+1} & \bar{\psi}_{km}^{(4)} &= G_{-k-1} P_k^{m+1}. \end{aligned} \quad (42)$$

The functions P_k^m are spherical harmonics defined in the following way

$$P_k^m = (k-m)! \sin^m \theta \left(\frac{d}{d \cos \theta} \right)^{k+m} \left(\frac{\cos^2 \theta - 1}{2^k \cdot k!} \right) \cdot e^{im\phi}. \quad (43)$$

It can be shown that

$$P_k^{-m} = (-1)^m P_k^{m*} \quad (44)$$

so that only the values of P_k^m for positive m need to be known. Furthermore

$$\int_0^\pi \int_0^{2\pi} P_k^m P_k^{m*} \sin \theta d\theta d\phi = \frac{4\pi}{2k+1} (k+m)!(k-m)!. \quad (45)$$

The functions F_k and G_k depend upon the radius r only and satisfy the relations

$$\begin{aligned} \frac{2\pi}{h} \left(\frac{E+eV}{c} + mc \right) F_k + \frac{dG_k}{dr} - \frac{k}{r} G_k &= 0 \\ -\frac{2\pi}{h} \left(\frac{E+eV}{c} - mc \right) G_k + \frac{dF_k}{dr} + \left(\frac{k+2}{r} \right) F_k &= 0. \end{aligned} \quad (46)$$

For a hydrogen-like atom with the nuclear charge Ze the potential V is equal to eZ/r and so, if the following notation is used

$$\frac{2\pi}{h} \left(\frac{E}{c} + mc \right) = A^2; \quad \frac{2\pi}{h} \left(\frac{E}{c} - mc \right) = B^2; \quad \frac{2\pi e^2 Z}{hc} = \gamma = Z\alpha \quad (47)$$

where α is the Sommerfeld fine structure constant, then instead of (46)

$$\begin{aligned} \left(A^2 + \frac{\gamma}{r} \right) F_k + \frac{dG_k}{dr} - \frac{k}{r} G_k &= 0 \\ \left(B^2 + \frac{\gamma}{r} \right) G_k - \frac{dF_k}{dr} - \frac{k+2}{r} F_k &= 0. \end{aligned} \quad (48)$$

¹⁰ G. Wentzel, Zeits. f. Physik 40, 574 (1926).

¹¹ C. G. Darwin, reference 6.

The solutions (41) and (42) correspond to different values of the inner quantum number j . For the solution (41) $j = k + \frac{1}{2}$, for (42) $j = k - \frac{1}{2}$. Moreover, for the solution (41) $-k-1 \leq m \leq k$ which leads to $2k+2$ different solutions, whereas for the type (42) one has $-k \leq m \leq k-1$ i.e. $2k$ different solutions. In each case there are $2j+1$ solutions as it should be.

In the subsequent calculations the normalizing integrals for the proper functions (41) and (42) are used. These integrals were given by Darwin¹² For the solution (41)

$$C'_{km} = \int \bar{\phi}_{km} \bar{\psi}_{km} d\tau = 4\pi(k+m+1)!(k-m)! \int_0^\infty (F_k^2 + G_k^2) r^2 dr \quad (49)$$

and for the solution (42)

$$C''_{km} = \int \bar{\phi}_{km} \bar{\psi}_{km} d\tau = 4\pi(k+m)!(k-m-1)! \int_0^\infty (F_{-k-1}^2 + G_{-k-1}^2) r^2 dr. \quad (50)$$

It is also to be noted that the solutions (41) and (42) form an orthogonal set of functions, i. e.

$$\int \bar{\phi}_{kmj}(E) \bar{\psi}_{k'm'j'}(E') d\tau = 0 \quad (51)$$

except for $E=E'$, $k=k'$, $m=m'$ and $j=j'$ (j -inner quantum number).

Darwin has also shown that for $E < mc^2$ a hydrogen-like atom has a set of discrete proper values of E , which correspond to the solutions (41) and (42). For $E > mc^2$ there are solutions for each value of E . This last condition corresponds to the existence of a continuous spectrum. It can be shown that in this latter case F_k and G_k are complex functions, which to the first approximation correspond to spherical waves diverging from the nucleus (or converging towards the nucleus).

To find the approximate forms of F_k and G_k for $r \rightarrow \infty$ all terms in Eqs. (48) with r in the denominator can be omitted in the first approximation. This leads to

$$A^2 F + dG/dr = 0; \quad B^2 G - dF/dr = 0 \quad (52)$$

with both A^2 and B^2 positive. Hence

$$A^2 F + \frac{1}{B^2} \frac{d^2 F}{dr^2} = 0; \quad B^2 G + \frac{1}{A^2} \frac{d^2 G}{dr^2} = 0 \quad (53)$$

and

$$F = ae^{iABr}; \quad G = be^{iABr}. \quad (54)$$

These values of F and G substituted into Eqs. (52) give

$$a = -ibB/A = -ibp \quad (55)$$

p is a small quantity and so $\bar{\psi}^{(1)}$ and $\psi^{(2)}$ are small compared with $\bar{\psi}^{(3)}$ and $\bar{\psi}^{(4)}$.

¹² C. G. Darwin, reference 6.

In the second approximation a and b can be considered as varying slowly with r and so all terms with a/r^2 , a'/r and a'' and analogous terms for b are to be omitted. If the values (53) and (54) are substituted into Eqs. (48) the above assumption leads to

$$a' + \frac{a}{r} \left[1 - \frac{i\gamma}{2} \left(\frac{A}{B} + \frac{B}{A} \right) \right] = 0 \quad (56)$$

and the same equation for b

If one puts

$$\frac{\gamma}{2} \left(\frac{A}{B} + \frac{B}{A} \right) = \delta \quad (57)$$

then the Eq. (56) takes the form

$$a' + \frac{a}{r} (1 - i\delta) = 0 \quad (58)$$

whence

$$a = C e^{i\delta \log r} / r. \quad (59)$$

Therefore finally

$$\begin{aligned} F &= -i p C e^{i(ABr + \delta \log r)} / r \\ G &= C e^{i(ABr + \delta \log r)} / r. \end{aligned} \quad (60)$$

On the basis of the notations (47) it can easily be found that AB is usually of the order 10^9 , whereas δ is, for high speed photoelectrons and low atomic numbers, small compared with unity. As the $\log r$ varies much more slowly than r it follows that $\delta \log r = \tau$ can be considered to this approximation as a constant.

All is now prepared for the actual calculation of the coefficient $A_{km}^+(E')$ in Eq. (40). These coefficients are given by Eq. (37), which, written in the developed form is

$$\begin{aligned} C_{km}(E') A_{km}(E') &= \int \bar{\phi}_{km}^{(1)}(E') \frac{\partial \bar{\psi}_{k_0}^{(1)}}{\partial x} e^{2\pi i z / \lambda} d\tau \\ &+ \int \bar{\phi}_{km}^{(2)}(E') \frac{\partial \bar{\psi}_{k_0}^{(2)}}{\partial x} e^{2\pi i z / \lambda} d\tau \\ &+ \int \bar{\phi}_{km}^{(3)}(E') \frac{\partial \bar{\psi}_{k_0}^{(3)}}{\partial x} e^{2\pi i z / \lambda} d\tau + \int \bar{\phi}_{km}^{(4)}(E') \frac{\partial \bar{\psi}_{k_0}^{(4)}}{\partial x} e^{2\pi i z / \lambda} d\tau \\ &- \frac{\pi}{\lambda} \left[-i \int \bar{\phi}_{km}^{(1)}(E') \bar{\psi}_{k_0}^{(2)} e^{2\pi i z / \lambda} d\tau + i \int \bar{\phi}_{km}^{(2)}(E') \bar{\psi}_{k_0}^{(1)} e^{2\pi i z / \lambda} d\tau \right. \\ &\left. - i \int \bar{\phi}_{km}^{(3)}(E') \bar{\psi}_{k_0}^{(4)} e^{2\pi i z / \lambda} d\tau + i \int \bar{\phi}_{km}^{(4)}(E') \bar{\psi}_{k_0}^{(3)} e^{2\pi i z / \lambda} d\tau \right] \quad (61) \end{aligned}$$

$$-\frac{i\pi}{\lambda} \left[\int \bar{\phi}_{km}^{(1)}(E') \bar{\psi}_{k_0}^{(4)} e^{2\pi iz/\lambda} d\tau + \int \bar{\phi}_{km}^{(2)}(E') \bar{\psi}_{k_0}^{(3)} e^{2\pi iz/\lambda} d\tau \right. \\ \left. + \int \bar{\phi}_{km}^{(3)}(E') \bar{\psi}_{k_0}^{(2)} e^{2\pi iz/\lambda} d\tau + \int \bar{\phi}_{km}^{(4)}(E') \bar{\psi}_{k_0}^{(1)} e^{2\pi iz/\lambda} d\tau \right].$$

The Eq. (61) follows from (37) if it is remembered that, according to Dirac¹³

$$\sigma_2 = \begin{vmatrix} 0 & -i & 0 & 0 \\ i & 0 & 0 & 0 \\ 0 & 0 & 0 & -i \\ 0 & 0 & i & 0 \end{vmatrix} \quad \text{and} \quad \rho_1 \sigma_1 = \begin{vmatrix} 0 & 0 & 0 & 1 \\ 0 & 0 & 1 & 0 \\ 0 & 1 & 0 & 0 \\ 1 & 0 & 0 & 0 \end{vmatrix}. \quad (62)$$

To simplify the calculations it will be supposed that the hydrogen-like atom considered is initially in the normal unexcited state. According to Darwin two possibilities are then to be considered¹⁴.

Either

$$\bar{\psi}_{k_0}^{(1)} = \frac{-i\gamma}{1+(1-\gamma^2)^{1/2}} P_1^0 r^\beta e^{-r/a_0} \quad \bar{\psi}_{k_0}^{(3)} = r^\beta e^{-r/a_0} \quad (63)$$

$$\bar{\psi}_{k_0}^{(2)} = \frac{-i\gamma}{1+(1-\gamma^2)^{1/2}} P_1^1 r^\beta e^{-r/a_0} \quad \bar{\psi}_{k_0}^{(4)} = 0$$

OR

$$\bar{\psi}_{k_0}^{(1)} = \frac{-i\gamma}{1+(1-\gamma^2)^{1/2}} P_1^{-1} r^\beta e^{-r/a} \quad \bar{\psi}_{k_0}^{(3)} = 0 \quad (64)$$

$$\bar{\psi}_{k_0}^{(2)} = \frac{-i\gamma}{1+(1-\gamma^2)^{1/2}} P_1^0 r^\beta e^{-r/a_0} \quad \bar{\psi}_{k_0}^{(4)} = -r^\beta e^{-r/a_0}$$

In the equations above β denotes $(1-\gamma^2)^{1/2}-1$ and a_0 is equal to a/Z where a is the radius of the first Bohr orbit.

Accordingly either

$$\frac{\partial \bar{\psi}_{k_0}^{(1)}}{\partial x} = \frac{-i\gamma}{1+(1-\gamma^2)^{1/2}} \frac{\partial}{\partial r} (r^{\beta-1} e^{-r/a_0}) P_1^0 r \sin \theta \cos \phi \quad (r P_1^0 = z) \\ \frac{\partial \bar{\psi}_{k_0}^{(2)}}{\partial x} = \frac{-i\gamma}{1+(1-\gamma^2)^{1/2}} \frac{\partial}{\partial r} (r^{\beta-1} e^{-r/a_0}) P_1^1 r \sin \theta \cos \phi - \frac{i\gamma}{1+(1-\gamma^2)^{1/2}} r^{\beta-1} e^{-r/a_0} \\ \frac{\partial \bar{\psi}_{k_0}^{(3)}}{\partial x} = \frac{\partial}{\partial r} (r^\beta e^{-r/a_0}) \quad (r P_1^1 = x + iy) \\ \frac{\partial \bar{\psi}_{k_0}^{(4)}}{\partial x} = 0 \quad (65)$$

¹³ P. A. M. Dirac, Proc. Roy. Soc. **117**, 680 (1928).

¹⁴ C. G. Darwin, l. c.

or

$$\begin{aligned}
 \frac{\partial \bar{\psi}_{k_0}^{(1)}}{\partial x} &= -\frac{i\gamma}{1+(1-\gamma^2)^{1/2}} \frac{\partial}{\partial r} (r^{\beta-1} e^{-r/a_0}) P_1^{-1} r \sin \theta \cos \phi + \frac{i\gamma}{1+(1-\gamma^2)^{1/2}} r^{\beta-1} e^{-r/a_0} \\
 \frac{\partial \bar{\psi}_{k_0}^{(2)}}{\partial x} &= -\frac{i\gamma}{1+(1-\gamma^2)^{1/2}} \frac{\partial}{\partial r} (r^{\beta-1} e^{-r/a_0}) P_1^0 r \sin \theta \cos \phi \quad (-r P_1^{-1} = x - i\gamma) \\
 \frac{\partial \bar{\psi}_{k_0}^{(3)}}{\partial x} &= 0 \\
 \frac{\partial \bar{\psi}_{k_0}^{(4)}}{\partial x} &= -\frac{\partial}{\partial r} (r^\beta e^{-r/a_0}).
 \end{aligned} \tag{66}$$

These two possibilities will be considered separately.

The integrals in Eq. (61) differ from zero only for certain definite values of k and m . The next step of the computations consists in determining these values.

On account of the appearance of the factor $e^{2\pi iz/\lambda}$ in the integrands there are two possible ways of performing the computations. Either as Sommerfeld has done, one can develop the function $e^{2\pi i r \cos \theta / \lambda}$ into a series of powers of $r \cos \theta / \lambda$ and then can calculate the possible values of the coefficients $A_{km}(E')$ on the basis of this expansion or one can start from the function $e^{2\pi i r \cos \theta / \lambda}$ itself. This last method was used recently by Carrelli.¹⁵ Both these methods lead to the same results on account of the absolute and uniform convergence of the series

$$1 + \frac{x}{1!} + \frac{x^2}{2!} + \frac{x^3}{3!} + \dots \tag{67}$$

for all points of the x plane. The series (67) can be therefore integrated term by term, which gives the same result as the integration of the function e^x itself. The same applies to the products of the exponential by various spherical harmonics and the products of the expansion (67) by these harmonics.

Carrelli finds the coefficients $A_{km}(E')$ in the form of the functions of a quantity R equal to

$$\lambda/2\pi (1/a_0 + iAB)$$

and then develops these functions into series of R . Sommerfeld's method leads immediately to the power series of R as the value for $A_{km}(E')$. It is obvious that both these power series are identical.

Carrelli has computed only the coefficients $A_{11}(E')$ and $A_{21}(E')$ on the basis of the Schrödinger equation and in his calculations took into account only the first two terms of the power series expansions for each of these coefficients. These terms were of the order of $1/R^2$ and $1/R^4$ for the coefficient $A_{11}(E')$ and of the orders of $1/R^3$ and $1/R^5$ for the coefficient $A_{21}(E')$.

¹⁵ A. Carrelli, *Zeits. f. Phys.* **56**, 694 (1929).

To be consistent Carrelli should also find the first term of the expansion, which corresponds to the coefficient $A_{31}(E')$, whose order is $1/R^4$ and the first term of the expansion for $A_{41}(E')$ which is of the order of $1/R^5$. These last two terms were neglected by Carrelli and this invalidates his result. To appreciate the influence of the above mentioned terms one has to consider that in Carrelli's case the perturbed wave function can be written in the form

$$\psi = A_{11}Q_1^1 \cos \phi + A_{21}Q_2^1 \cos \phi + A_{31}Q_{31}^1 \cos \phi + A_{41}Q_4^1 \cos \phi \quad (68)$$

where Q_k^m denote the spherical harmonics used by Carrelli. The values of the harmonics in (68) are

$$\begin{aligned} Q_1^1 &= \sin \theta & Q_2^1 &= 3 \sin \theta \cos \theta \\ Q_3^1 &= (3/2) \sin \theta (5 \cos^2 \theta - 1) & Q_4^1 &= (5/2) \sin \theta \cos \theta (7 \cos^2 \theta - 3) \end{aligned} \quad (69)$$

whence

$$\begin{aligned} \psi = \sin \theta \cos \phi \left\{ A_{11} + 3A_{21} \cos \theta + \frac{15}{2}A_{31} \cos^2 \theta \right. \\ \left. - \frac{3}{2}A_{31} + \frac{35}{2} \cos^3 \theta A_{41} - \frac{15}{2}A_{41} \cos \theta \right\}. \end{aligned} \quad (70)$$

It follows, that the terms omitted by Carrelli were

$$-\frac{3}{2}A_{31} \quad \text{and} \quad -\frac{15}{2}A_{41} \cos \theta.$$

In the present paper Sommerfeld's method of computation will be used. To obtain the degree of approximation comparable with that of Carrelli the exponential $e^{2\pi i r \cos \theta / \lambda}$ will be developed into a power series, whose first four terms will be retained. Thus

$$e^{2\pi i r \cos \theta / \lambda} = 1 + \frac{2\pi i r}{\lambda} \cos \theta - \frac{2\pi^2 r^2}{\lambda^2} \cos^2 \theta - \frac{4\pi^3 i r^3}{3\lambda^3} \cos^3 \theta. \quad (71)$$

To find the values of k and m for which Eq. (61) differs from zero it is sufficient to take into account the orthogonality relations for the functions P_k^m , as Sommerfeld has done. Those relations are

$$\int_0^\pi \int_0^{2\pi} P_k^m P_l^{n*} \sin \theta d\theta d\phi = 0 \quad \left(\begin{matrix} k \neq l \\ m \neq n \end{matrix} \right). \quad (72)$$

Furthermore in Eqs. (65) and (66) $\frac{1}{2}(e^{i\phi} + e^{-i\phi})$ can be written instead of $\cos \phi$. The values of the functions P_k^m for those values of k and m which enter into consideration in this paper are given below

$$\begin{aligned} P_0^0 &= 1 & P_1^1 &= \sin \theta e^{i\phi} \\ P_1^0 &= \cos \theta & P_2^1 &= 3 \sin \theta \cos \theta e^{i\phi} \\ P_2^0 &= 3 \cos^2 \theta - 1 & P_3^1 &= 3 \sin \theta (5 \cos^2 \theta - 1) e^{i\phi} \end{aligned}$$

$$\begin{aligned}
P_3^0 &= 3(5 \cos^3 \theta - 3 \cos \theta) & P_4^1 &= 15 \sin \theta (7 \cos^3 \theta - 3 \cos \theta) e^{i\phi} \\
P_4^0 &= 3(35 \cos^4 \theta - 30 \cos^2 \theta + 3) & & \\
P_2^2 &= 3 \sin^2 \theta e^{2i\phi} & & \\
P_3^2 &= 15 \sin^2 \theta \cos \theta e^{2i\phi} & & \\
P_4^2 &= 15 \sin^2 \theta (7 \cos^2 \theta - 1) e^{2i\phi}.
\end{aligned} \tag{73}$$

It will be supposed now that the initial state of the atom is given by Eqs. (63) and (65). The two types of the solutions, given by the Eqs. (41) and (42) have to be considered separately. The reasoning quite similar to that of Sommerfeld shows that for the solution (41) the coefficients $A'_{km}(E')$ (the accent is used to denote the first type of the solution) are different from zero for

$$\begin{aligned}
k=0 & \quad m=-1 & k=3 & \quad m=\pm 1 \\
k=1 & \quad m=\pm 1 & k=4 & \quad m=\pm 1 \\
k=2 & \quad m=\pm 1 & &
\end{aligned} \tag{74}$$

Similarly for the solution (42) the coefficients $A''_{km}(E')$ (two accents denote the second type of solution) are different from zero for

$$\begin{aligned}
k=1 & \quad m=-1 & k=4 & \quad m=\pm 1 \\
k=2 & \quad m=\pm 1 & k=5 & \quad m=\pm 1 \\
k=3 & \quad m=\pm 1 & &
\end{aligned} \tag{75}$$

It is to be noted that for the term $-4\pi^3 i r^3 \cos^3 \theta / 3\lambda^3$ in the expansion (71) only the integrals in Eq. (61) with the greatest absolute value were taken into account.

For the sake of brevity the following notations are used in the subsequent calculations (κ is equal to AB).

$$\int_0^\infty \frac{\partial}{\partial r} (r^{\beta-1} e^{-r/a_0}) e^{-i\kappa r} r^2 dr = Q_1 \tag{76} \quad \int_0^\infty r^\beta e^{-r/a_0} e^{-i\kappa r} r^2 dr = Q_6 \tag{81}$$

$$\int_0^\infty \frac{\partial}{\partial r} (r^{\beta-1} e^{-r/a_0}) e^{-i\kappa r} r^3 dr = Q_2 \tag{77} \quad \int_0^\infty \frac{\partial}{\partial r} (r^\beta e^{-r/a_0}) e^{-i\kappa r} r dr = Q_7 \tag{82}$$

$$\int_0^\infty \frac{\partial}{\partial r} (r^{\beta-1} e^{-r/a_0}) e^{-i\kappa r} r^4 dr = Q_3 \tag{78} \quad \int_0^\infty \frac{\partial}{\partial r} (r^\beta e^{-r/a_0}) e^{-i\kappa r} r^2 dr = Q_8 \tag{83}$$

$$\int_0^\infty r^\beta e^{-r/a_0} e^{-i\kappa r} dr = Q_4 \tag{79} \quad \int_0^\infty \frac{\partial}{\partial r} (r^\beta e^{-r/a_0}) e^{-i\kappa r} r^3 dr = Q_9 \tag{84}$$

$$\int_0^\infty r^\beta e^{-r/a_0} e^{-i\kappa r} r dr = Q_5 \tag{80} \quad \int_0^\infty \frac{\partial}{\partial r} (r^\beta e^{-r/a_0}) e^{-i\kappa r} r^4 dr = Q_{10}. \tag{85}$$

If the values (73) of the spherical harmonics and the normalizing integrals (49) and (50) are taken into account then with regard to Eq. 61 it follows after some easy calculations that

$$A'_{0,-1}(E') = \frac{\pi}{\lambda} Q_5 \left(i + \frac{\gamma p}{6} \right) + \frac{\pi^2}{3\lambda^2} Q_6 (2p + i\gamma) \quad (86)$$

$$A'_{1,1}(E') = -\frac{i\gamma p}{12} Q_1 + \frac{\pi^2}{30\lambda^2} i\gamma p Q_3 + \frac{Q_7}{6} - \frac{\pi^2}{15\lambda^2} Q_9 + \frac{i\pi^2}{15\lambda^2} \gamma p Q_6 - \frac{\pi\gamma}{6\lambda} Q_5 \quad (87)$$

$$A'_{1,-1}(E') = \frac{i\gamma p}{12} Q_1 - \frac{\pi^2}{30\lambda^2} i\gamma p Q_3 - \frac{Q_7}{6} + \frac{\pi^2}{15\lambda^2} Q_9 - \frac{2\pi^2}{3\lambda^2} Q_6 + \frac{\pi\gamma}{6\lambda} Q_5 \quad (88)$$

$$A'_{2,1}(E') = \frac{\pi\gamma p}{30\lambda} Q_2 + \frac{i\pi}{\lambda} Q_8 - \frac{\pi^2}{15\lambda^2} i\gamma Q_6 - \frac{2i\pi^3}{105\lambda^3} Q_{10} \quad (89)$$

$$A'_{3,1}(E') = -\frac{\pi^2}{210\lambda^2} i\gamma p Q_3 - \frac{\pi^2}{105\lambda^2} Q_9 \quad (90)$$

$$A'_{2,-1}(E') = -\frac{\pi\gamma p}{30\lambda} Q_2 - \frac{i\pi}{\lambda} Q_8 + \frac{\pi^2}{15\lambda^2} i\gamma Q_6 + \frac{2i\pi^3}{105\lambda^3} Q_{10} \quad (91)$$

$$A'_{3,-1}(E') = -\frac{\pi^2}{210\lambda^2} i\gamma p Q_3 + \frac{\pi^2}{105\lambda^2} Q_9 \quad (92)$$

$$A'_{4,1}(E') = -\frac{2i\pi^3}{2835\lambda^3} Q_{10} \quad (93)$$

$$A'_{4,-1}(E') = \frac{2i\pi^3}{2835\lambda^3} Q_{10} \quad (94)$$

$$A''_{1,-1}(E') = \frac{i\gamma p}{6} Q_1 - \frac{\pi^2}{15\lambda^2} i\gamma p Q_3 + \frac{i\gamma p}{2} Q_4 - \frac{Q_7}{3} + \frac{2\pi^2}{15\lambda^2} Q_9 + \frac{2\pi^2}{3\lambda^2} Q_6 \\ + \frac{\pi}{\lambda} Q_5 \left(ip - \frac{\gamma}{6} \right) \quad (95)$$

$$A''_{2,1}(E') = \frac{\pi\gamma p}{30\lambda} Q_2 + \frac{i\pi}{15\lambda} Q_8 + \frac{\pi\gamma p}{6\lambda} Q_5 - \frac{\pi^2}{15\lambda^2} i\gamma A_6 - \frac{2i\pi^3}{105\lambda^3} Q_{10} \quad (96)$$

$$A''_{2,-1}(E') = -\frac{\pi\gamma p}{30\lambda} Q_2 - \frac{\pi\gamma p}{6\lambda} Q_5 - \frac{i\pi}{5\lambda} Q_8 - \frac{2\pi^2}{3\lambda^2} Q_6 (p + i\gamma) + \frac{2i\pi^3}{35\lambda^3} Q_{10} \quad (97)$$

$$A''_{3,1}(E') = \frac{\pi^2 i\gamma p}{105\lambda^2} Q_3 - \frac{2\pi^2}{105\lambda^2} Q_9 + \frac{\pi^2}{15\lambda^2} i\gamma p Q_6 \quad (98)$$

$$A''_{3,-1}(E') = -\frac{2\pi^2}{105\lambda^2} i\gamma p Q_3 + \frac{4\pi^2}{105\lambda^2} Q_9 \quad (99)$$

$$A''_{4,1}(E') = -\frac{2i\pi^3}{945\lambda^3} Q_{10} \quad (100)$$

$$A''_{4,-1}(E') = \frac{2i\pi^3}{567\lambda^3} Q_{10} \quad (101)$$

$$\left. \begin{aligned} A''_{5,1}(E') &= 0 \\ A''_{5,-1}(E') &= 0 \end{aligned} \right\} \quad (102)$$

If it is taken into account that

$$\frac{\partial}{\partial r}(r^\beta e^{-r/a_0}) = \left(\beta r^{\beta-1} - \frac{r^\beta}{a_0} \right) e^{-r/a_0} \quad (103)$$

and

$$\frac{\partial}{\partial r}(r^{\beta-1} e^{-r/a_0}) = \left((\beta-1)r^{\beta-2} - \frac{r^{\beta-1}}{a_0} \right) e^{-r/a_0} \quad (104)$$

then with the notation $q = 1/a_0 + i\kappa$ and

$$S = \int_0^\infty r^\beta e^{-qr} dr \quad (105)$$

it can be shown by integration by parts that

$$Q_1 = -\frac{S}{a_0 q} (1 + a_0 q) \quad (106) \quad Q_6 = \frac{2S}{q^2} \quad (111)$$

$$Q_2 = -\frac{S}{a_0 q^2} (2 + a_0 q) \quad (107) \quad Q_7 = -\frac{S}{a_0 q} \left(1 + \gamma^2 \frac{i a_0 k}{2} \right) \quad (112)$$

$$Q_3 = -\frac{2S}{a_0 q^3} (3 + a_0 q) \quad (108) \quad Q_8 = -\frac{2S}{a_0 q^2} \left[1 + \frac{i\gamma^2}{2} \left(i + \frac{a_0 k}{2} \right) \right] \quad (113)$$

$$Q_4 = S \quad (109) \quad Q_9 = -\frac{6S}{a_0 q^3} \quad (114)$$

$$Q_5 = \frac{S}{q} \quad (110) \quad Q_{10} = -\frac{24S}{a_0 q^4} \quad (115)$$

The expressions (106) (115) were simplified by taking into account the fact that β is equal to $(1 - \gamma^2)^{1/2} - 1$ or approximately to $-\gamma^2/2$ and is therefore very small. Accordingly it was put equal to zero in all the Q 's with the exception of Q_7 and Q_8 whose values, on the evidence of the expressions (86)-(102) are the most important ones. Therefore in the expressions (112) and (113) β was put equal to $-\gamma^2/2$.

On the basis of Eqs. (41) and (42) together with (40) one can write if the radial parts of the functions $\psi_{km}(E')$ which are common to all terms on account of the expressions (60), are omitted

$$\begin{aligned} \bar{\psi}_3 \sim & A'_{0,-1}(E')(0-1+1)P_0^{-1} + A'_{1,-1}(E')(1-1+1)P_1^{-1} \\ & + A'_{1,1}(E')(1+1+1) \cdot P_1^1 + A_{2,1}(E')(2+1+1)P_2^1 + A'_{2,-1}(E')(2-1+1)P_2^{-1} \\ & + A'_{3,1}(E')(3+1+1)P_3^1 + A'_{3,-1}(E')(3-1+1)P_3^{-1} + A'_{4,1}(E')(4+1+1) \cdot P_4^1 \\ & + A'_{4,-1}(E')(4-1+1)P_4^{-1} + A''_{1,-1}(E')P_1^{-1} + A''_{2,1}(E')P_2^1 \\ & + A''_{2,-1}(E')P_2^{-1} + A''_{3,1}(E')P_3^1 + A''_{3,-1}(E')P_3^{-1} + A''_{4,1}(E')P_4^1 \\ & + A''_{4,-1}(E')P_4^{-1} = P_1^1 \cdot 3A'_{1,1}(E') + P_1^{-1} [A'_{1,-1}(E') + A'_{1,-1}(E')] \\ & + P_2^1 [4A'_{2,1}(E') + A''_{2,1}(E')] + P_2^{-1} [2A'_{2,-1}(E') + A''_{2,-1}(E')] \\ & + P_3^1 [5A'_{3,1}(E') + A''_{3,1}(E')] + P_3^{-1} [3A'_{3,-1}(E') + A''_{3,-1}(E')] \\ & + P_4^1 [6A'_{4,1}(E') + A''_{4,1}(E')] + P_4^{-1} [4A'_{4,-1}(E') + A''_{4,-1}(E')]. \end{aligned} \quad (116)$$

and

$$\begin{aligned}
 \psi_4 \sim & A'_{0,-1}(E')(0-1)P_0^0 + A'_{1,1}(E')(-1+1)P_1^2 + A'_{1,-1}(E')(-1-1)P_1^0 \\
 & + A'_{2,1}(E')(-2+1)P_2^2 + A'_{2,-1}(E')(-2-1)P_2^0 + A'_{3,1}(E')(-3+1)P_3^2 \\
 & + A'_{3,-1}(E')(-3-1)P_3^0 + A'_{4,1}(E')(-4+1)P_4^2 + A'_{4,-1}(E')(-4-1)P_4^0 \\
 & + A''_{1,-1}(E')P_1^0 + A''_{2,1}(E')P_2^2 + A''_{2,-1}(E')P_2^0 + A''_{3,1}(E')P_3^2 + A''_{3,-1}(E')P_3^0 \\
 & + A''_{4,1}(E')P_4^2 + A''_{4,-1}(E')P_4^0 = -P_0^0 A'_{0,-1}(E') + P_1^0 [A'_{1,-1}(E') \\
 & - 2A'_{1,1}(E')] + P_2^0 [A'_{2,-1}(E') - 3A'_{2,1}(E')] + P_2^2 [A'_{2,1}(E') - A'_{2,-1}(E')] \\
 & + P_3^0 [A'_{3,-1}(E') - 4A'_{3,1}(E')] + P_3^2 [A'_{3,1}(E') - 2A'_{3,-1}(E')] \\
 & + P_4^0 [A'_{4,-1}(E') - 5A'_{4,1}(E')] + P_4^2 [A'_{4,1}(E') - 3A'_{4,-1}(E')].
 \end{aligned} \quad (117)$$

With regard to $\bar{\psi}_1$ and $\bar{\psi}_2$ it is to be remembered that they are small, of the order of p , when compared with $\bar{\psi}_3, \bar{\psi}_4$. Therefore it is sufficient to compute for them only the terms with the greatest absolute values and hence only the terms with the coefficients $A'_{1,-1}(E'), A'_{1,1}(E')$ and $A''_{1,-1}(E')$ are considered. Thus

$$\begin{aligned}
 \bar{\psi}_1 = & -p \{ P_2^1 A'_{1,1}(E') + P_2^{-1} A'_{1,-1}(E') + P_0^{-1} (1-1) A''_{1,-1}(E') \} \\
 = & -p \{ P_2^1 A'_{1,1}(E') + P_2^{-1} A'_{1,-1}(E') \}
 \end{aligned} \quad (118)$$

and

$$\begin{aligned}
 \bar{\psi}_2 = & -p \{ P_2^2 A'_{1,1}(E') + P_2^0 A'_{1,-1}(E') + P_0^0 (-1-1+1) A''_{1,-1}(E') \} \\
 = & -p \{ P_2^2 A'_{1,1}(E') + P_2^0 A'_{1,-1}(E') - P_0^0 A''_{1,-1}(E') \}.
 \end{aligned} \quad (119)$$

If Eqs. (86) (102) and (106) (115) are taken into account and substituted into Eqs. (116) (119) then after some calculation

$$\bar{\psi}_1 = -p \sin \theta \cos \theta \cos \phi \quad (120)$$

$$\bar{\psi}_2 = -p \sin^2 \theta \cos \phi e^{i\phi} \quad (121)$$

$$\begin{aligned}
 \bar{\psi}_3 = & \left(1 + \gamma^2 \frac{i a_0 \kappa}{2} \right) \sin \theta \cos \phi - \frac{i \gamma p}{2} (1 + a_0 q) \sin \theta \cos \phi + \frac{i \gamma p a_0 q}{2} \sin \theta e^{-i\phi} \\
 & + \frac{4\pi i}{\lambda q} \sin \theta \cos \theta \cos \phi \left[1 + \frac{i \gamma^2}{2} \left(i + \frac{a_0 \kappa}{2} \right) \right] + \frac{\pi \gamma p}{\lambda q} (2 + a_0 q) \sin \theta \cos \theta \cos \phi \\
 & - \frac{\pi \gamma a_0}{\lambda} \sin \theta \cos \theta \cos \phi - \frac{12\pi^2}{\lambda^2 q^2} \sin \theta \cos^2 \theta \cos \phi \\
 & + \frac{2\pi^2}{\lambda^2 q^2} (3 + a_0 q) i \gamma p \sin \theta \cos^2 \theta \cos \phi - \frac{2\pi^2}{\lambda^2} \frac{a_0}{q} i \gamma p \sin \theta \cos^2 \theta e^{i\phi} \\
 & + \frac{\pi a_0}{2\lambda} \sin \theta (\gamma e^{i\phi} + 2 i p e^{-i\phi}) - \frac{2\pi^2}{\lambda^2} \frac{a_0}{q} \sin \theta \cos \theta (2 p e^{-i\phi} - i \gamma e^{i\phi}) \\
 & - \frac{32 i \pi^3}{\lambda^3 q^3} \sin \theta \cos^3 \theta \cos \phi
 \end{aligned} \quad (122)$$

$$\psi_4 = \frac{\pi i a_0}{\lambda} - \frac{i \gamma p a_0 q}{2} \cos \theta. \quad (123)$$

In the Eq. (123) only the terms with the greatest absolute values were taken into account, the rest can be safely omitted to the present approximation. Moreover in all the four Eqs. (120)–(123) the common factor $-S/a_0 q$ was omitted.

The Eqs. (120), (121), (122) and (123) represent a spherical material wave diverging from the considered atom, whose amplitude depends upon the direction in space. This can be seen at once if one takes into account the neglected common radial factors. Therefore the spatial distribution of the photoelectrons (whose kinetic energy and velocity do not depend upon the direction of emission as can be seen from the foregoing discussion) is given by the intensity of these waves or by the density of electric charge emitted in a considered direction, which is equal to

$$-e\bar{\phi}\bar{\psi} = -e(\bar{\phi}_1\bar{\psi}_1 + \bar{\phi}_2\bar{\psi}_2 + \bar{\phi}_3\bar{\psi}_3 + \bar{\phi}_4\bar{\psi}_4). \quad (10)$$

It is to be remembered that ϕ is conjugate complex with regard to ψ . According to the relations (120)–(123)

$$\begin{aligned} \phi\psi \sim & p^2 \sin^2 \theta \cos^2 \phi + \frac{\pi^2 a_0^2}{\lambda^2} + \frac{\gamma^2 p^2}{4} a_0^2 q q^* \cos^2 \theta - \frac{\pi a_0^2}{2\lambda} \gamma p (q + q^*) \cos \theta \\ & + \sin^2 \theta \cos^2 \phi + \frac{16\pi^2}{\lambda^2 q q^*} \sin^2 \theta \cos^2 \theta \cos^2 \phi - \frac{4\pi i}{\lambda q q^*} (q - q^*) \sin^2 \theta \cos \theta \cos^2 \phi \\ & + \frac{2\pi a_0 k \gamma^2}{\lambda q q^*} (q + q^*) \sin^2 \theta \cos \theta \cos^2 \phi + \left[\frac{2\pi i \gamma^2}{\lambda q q^*} (q - q^*) \right. \\ & \left. - \frac{\pi \gamma^2 a_0 k}{\lambda q q^*} (q + q^*) \right] \sin^2 \theta \cos \theta \cos^2 \phi - \frac{12\pi^2}{\lambda^2 q^2 q^{*2}} (q^2 + q^{*2}) \sin^2 \theta \cos^2 \theta \cos^2 \phi \\ & + \frac{a_0 i \gamma p}{2} (q^* - q) \sin^2 \theta \cos^2 \phi + \frac{2\pi \gamma p}{\lambda} \left(a_0 + \frac{q + q^*}{q q^*} \right) \sin^2 \theta \cos \theta \cos^2 \phi \\ & - \frac{2\pi a_0 \gamma}{\lambda} \sin^2 \theta \cos^2 \theta \cos^2 \phi + \frac{i \gamma p a_0}{2} (q e^{-i\phi} - q^* e^{i\phi}) \sin^2 \theta \cos \phi \\ & + \frac{\pi a_0}{\lambda} (\gamma \cos \phi + 2p \sin \phi) \sin^2 \theta \cos \phi + \frac{6\pi^2 i}{\lambda^2 q^2 q^{*2}} (q^{*2} - q^2) \gamma p \sin^2 \theta \cos^2 \theta \cos^2 \phi \\ & - \frac{2\pi^2}{\lambda^2} \frac{a_0 i \gamma p}{q q^*} (q - q^*) \sin^2 \theta \cos^2 \theta \cos^2 \phi - \frac{4\pi^2}{\lambda^2} \frac{a_0 p}{q q^*} (q e^{i\phi} + q^* e^{-i\phi}) \sin^2 \theta \cos^2 \theta \cos \phi \\ & + \frac{2\pi^2}{\lambda^2} \frac{a_0 i \gamma}{q q^*} (q^* e^{i\phi} - q e^{-i\phi}) \sin^2 \theta \cos^2 \theta \cos \phi \\ & + \frac{32}{\lambda^3 (q q^*)^3} i \pi^3 (q^3 - q^{*3}) \sin^2 \theta \cos^3 \theta \cos^2 \phi \end{aligned} \quad (124)$$

$$-\frac{2\pi^2 a_0 i \gamma p}{\lambda^2} \sin^2 \theta \cos^2 \theta \cos \phi (e^{-i\phi}/q - e^{-i\phi}/q^*)$$

$$+\frac{48i\pi^3}{\lambda^3 q q^*} \left(\frac{1}{q} - \frac{1}{q^*} \right) \sin^2 \theta \cos^3 \theta \cos^2 \phi.$$

If on the other hand the initial state of the atom is described by Eqs. (64) and (66) then it is found that for the solutions of the type (41) the coefficients $A'_{km}(E')$ are different from zero for

$$\begin{array}{lll} k=0 & m=0 & k=3 \quad m=0, -2 \\ k=1 & m=0, -2 & k=4 \quad m=0, -2 \\ k=2 & m=0, -2 & \end{array} \quad (125)$$

whereas for the type (42) $A''_{km}(E')$ differ from zero for

$$\begin{array}{lll} k=1 & m=0 & k=3 \quad m=0, -2 \\ k=2 & m=0, -2 & k=5 \quad m=0, -2 \\ k=3 & m=0, -2 & \end{array} \quad (126)$$

After some calculations quite similar to the ones given previously for the foregoing possibility it follows that in this second case

$$\bar{\psi}_1 = p \sin^2 \theta \cos \phi e^{-i\phi}$$

$$\bar{\psi}_2 = -p \sin \theta \cos \theta \cos \phi \quad (127)$$

$$\bar{\psi}_3 = \frac{\pi i a_0}{\lambda} - \frac{i \gamma p a_0 q}{2} \cos \theta \quad (128)$$

$$\bar{\psi}_4 = - \left\{ \left(1 + \frac{\gamma^2 i a_0 q}{2} \right) \sin \theta \cos \phi - \frac{i \gamma p}{2} (1 + a_0 q) \sin \theta \cos \phi + \frac{i \gamma p a_0 q}{2} \sin \theta e^{i\phi} \right. \quad (129)$$

$$+ \frac{4\pi i}{\lambda q} \sin \theta \cos \theta \cos \phi \left[1 + \frac{i \gamma^2}{2} \left(i + \frac{a_0 q}{2} \right) \right] + \frac{\pi \gamma p}{\lambda q} (2 + a_0 q) \sin \theta \cos \theta \cos \phi$$

$$- \frac{\pi \gamma a_0}{\lambda} \sin \theta \cos \theta \cos \phi - \frac{12\pi^2}{\lambda^2 q^2} \sin \theta \cos^2 \theta \cos \phi + \frac{2\pi^2}{\lambda^2 q^2} (3 + a_0 q) i \gamma p \sin \theta \cos^2 \theta \cos \phi$$

$$- \frac{2\pi^2}{\lambda^2} \frac{a_0}{q} i \gamma p \sin \theta \cos^2 \theta e^{-i\phi} + \frac{\pi a_0}{2\lambda} \sin \theta (\gamma e^{-i\phi} + 2 p i e^{i\phi}) \quad (130)$$

$$\left. - \frac{2\pi^2}{\lambda^2} \frac{a_0}{q} (2 p e^{i\phi} - i \gamma e^{-i\phi}) \sin \theta \cos \theta - \frac{32 i \pi^3}{\lambda^3 q^3} \sin \theta \cos^3 \theta \cos \phi \right\}$$

Therefore in this case

$$\phi \psi = p^2 \sin^2 \theta \cos^2 \phi + \frac{\pi^2 a_0^2}{\lambda^2} + \frac{\gamma^2 p^2 a_0^2 q q^*}{4} \cos^2 \theta - \frac{\pi a_0^2 \gamma p}{2\lambda} (q + q^*) \cos \theta$$

$$\begin{aligned}
& + \sin^2 \theta \cos^2 \phi + \frac{16\pi^2}{\lambda^2 q q^*} \sin^2 \theta \cos^2 \theta \cos^2 \phi - \frac{4\pi i}{\lambda q q^*} (q - q^*) \sin^2 \theta \cos \theta \cos^2 \phi \\
& + \frac{2\pi a_0 \kappa \gamma^2}{\lambda q q^*} (q + q^*) \sin^2 \theta \cos \theta \cos^2 \phi + \left[\frac{2\pi i \gamma^2}{\lambda q q^*} (q - q^*) \right. \\
& \left. - \frac{\pi \gamma^2 a_0 \kappa}{\lambda q q^*} (q + q^*) \right] \sin^2 \theta \cos \theta \cos^2 \phi - \frac{12\pi^2}{\lambda^2 (q q^*)^2} (q^2 + q^{*2}) \sin^2 \theta \cos^2 \theta \cos^2 \phi \\
& + \frac{a_0 i \gamma p}{2} (q^* - q) \sin^2 \theta \cos^2 \phi + \frac{2\pi \gamma p}{\lambda} \left(a_0 + \frac{q + q^*}{q q^*} \right) \sin^2 \theta \cos \theta \cos^2 \phi \\
& - \frac{2\pi \gamma a_0}{\lambda} \sin^2 \theta \cos \theta \cos^2 \phi + \frac{i \gamma p a_0}{2} (q e^{i\phi} - q^* e^{-i\phi}) \sin^2 \theta \cos \phi \\
& + \frac{\pi a_0}{\lambda} \sin^2 \theta \cos \phi (\gamma \cos \phi - 2p \sin \phi) + \frac{6\pi^2 i}{\lambda^2 (q q^*)^2} (q^{*2} - q^2) \gamma p \sin^2 \theta \cos^2 \theta \cos^2 \phi \\
& + \frac{2\pi^2 a_0 i \gamma p}{\lambda^2 q q^*} (q^* - q) \sin^2 \theta \cos^2 \theta \cos^2 \phi - \frac{4\pi^2}{\lambda^2} \frac{a_0 p}{q q^*} (q e^{-i\phi} + q^* e^{i\phi}) \sin^2 \theta \cos^2 \theta \cos \phi \\
& + \frac{2\pi^2}{\lambda^2} \frac{a_0 i \gamma}{q q^*} (q^* e^{-i\phi} - q e^{i\phi}) \sin^2 \theta \cos^2 \theta \cos \phi \\
& + \frac{32 i \pi^3}{\lambda^3 (q q^*)^3} (q^3 - q^{*3}) \sin^2 \theta \cos^3 \theta \cos^2 \phi \\
& - \frac{2\pi^2 a_0 i \gamma p}{\lambda^2} \sin^2 \theta \cos^2 \theta \cos \phi (e^{-i\phi}/q - e^{i\phi}/q^*) \\
& + \frac{48 i \pi^3}{\lambda^3 q q^*} \left(\frac{1}{q} - \frac{1}{q^*} \right) \sin^2 \theta \cos^3 \theta \cos^2 \phi.
\end{aligned} \tag{131}$$

According to G. Wentzel¹⁶ the average of the expressions (124) and (131) is to be taken to find the real spatial distribution of the photoelectrons. Therefore this distribution is given by

$$\begin{aligned}
\phi \psi \sim & p^2 \sin^2 \theta \cos^2 \phi + \frac{\pi^2 a_0^2}{\lambda^2} + \frac{\gamma^2 p^2 a_0^2 q q^*}{4} \cos^2 \theta - \frac{\pi a_0^2 \gamma p}{2\lambda} (q + q^*) \cos \theta \\
& + \sin^2 \theta \cos^2 \phi + \frac{16\pi^2}{\lambda^2 q q^*} \sin^2 \theta \cos^2 \theta \cos^2 \phi - \frac{4\pi i}{\lambda q q^*} (q - q^*) \sin^2 \theta \cos \theta \cos^2 \phi \\
& + \frac{\pi a_0 \kappa \gamma^2}{\lambda q q^*} (q + q^*) \sin^2 \theta \cos \theta \cos^2 \phi + \frac{2\pi i \gamma^2}{\lambda q q^*} (q - q^*) \sin^2 \theta \cos \theta \cos^2 \phi \\
& + \frac{a_0 i \gamma p}{2} (q^* - q) \sin^2 \theta \cos^2 \phi - \frac{12\pi^2}{\lambda^2 (q q^*)^2} (q^2 + q^{*2}) \sin^2 \theta \cos^2 \theta \cos^2 \phi
\end{aligned}$$

¹⁶ G. Wentzel, l. c.

$$\begin{aligned}
& -\frac{2\pi\gamma a_0}{\lambda}(1-p)\sin^2\theta\cos\theta\cos^2\phi \\
& +\frac{2\pi\gamma p}{\lambda}\left(\frac{q+q^*}{qq^*}\right)\sin^2\theta\cos\theta\cos^2\phi+\frac{i\gamma pa_0}{2}(q-q^*)\sin^2\theta\cos\phi \\
& +\frac{\pi a_0\gamma}{2}\sin^2\theta\cos^2\phi+\frac{6\pi^2 i(q^{*2}-q^2)}{\lambda^2(qq^*)^2}\gamma p\sin^2\theta\cos^2\theta\cos^2\phi \\
& -\frac{4\pi^2}{\lambda^2}a_0 p\left(\frac{q+q^*}{qq^*}\right)\sin^2\theta\cos^2\theta\cos^2\phi+\frac{2\pi^2}{\lambda^2}\frac{a_0 i\gamma}{qq^*}(q^*-q)\sin^2\theta\cos^2\theta\cos^2\phi \\
& +\frac{32i\pi^3}{\lambda^3(qq^*)^3}(q^3-q^{*3})\sin^2\theta\cos^3\theta\cos^2\phi \\
& +\frac{48i\pi^3}{\lambda^3 qq^*}\left(\frac{1}{q}-\frac{1}{q^*}\right)\sin^2\theta\cos^2\theta\cos^2\phi.
\end{aligned} \tag{132}$$

If the notations used by Sommerfeld are adopted, then

$$a_0 = a/Z; \quad q = Z/a + i\kappa; \quad \gamma = \alpha Z \tag{133}$$

and so

$$\begin{aligned}
q+q^* &= 2Z/a; & q-q^* &= 2i\kappa; & qq^* &= Z^2/a^2 + \kappa^2; \\
q^2-q^{*2} &= 4i\kappa Z/a; & q^2+q^{*2} &= 2(Z^2/a^2 - \kappa^2); & q^3-q^{*3} &= 2i\kappa(3Z^2/a^2 - \kappa^2);
\end{aligned} \tag{134}$$

Moreover, according to Eq. (55)

$$p = \frac{B}{A} = \left(\frac{E' - mc^2}{E' + mc^2} \right)^{1/2} = \frac{\kappa}{A^2} \cong \frac{\kappa h}{4\pi mc} = \frac{\alpha \kappa a}{2} \tag{135}$$

but $E' - mc^2$ is equal to the kinetic energy of the photoelectron, $E' \sim mc^2$ and therefore

$$p \cong \left(\frac{mv^2}{4mc^2} \right)^{1/2} = \frac{v}{2c}. \tag{136}$$

Substitution of these values into Eq. (132) leads

$$\begin{aligned}
\phi\psi &\sim \sin^2\theta\cos^2\phi\left(1+p^2+\frac{\pi a\alpha}{\lambda}\right) + \sin^2\theta\cos\theta\cos^2\phi\left\{\frac{8\pi\kappa}{\lambda(Z^2/a^2+\kappa^2)}\right. \\
& +\frac{2\pi\alpha Z^2}{\lambda(Z^2/a^2+\kappa^2)}\frac{p}{a}-\frac{2\pi\kappa\gamma^2}{\lambda(Z^2/a^2+\kappa^2)}-\frac{2\pi a\alpha}{\lambda}(1-p)\left.\right\} + \sin^2\theta\cos^2\theta\cos^2\phi \\
& \cdot \left\{\frac{48\pi^2\kappa^2}{\lambda^2(Z^2/a^2+\kappa^2)^2}-\frac{8\pi^2}{\lambda^2(Z^2/a^2+\kappa^2)}+\frac{4\pi^2 a\alpha\kappa}{\lambda^2(Z^2/a^2+\kappa^2)}-\frac{24\pi^2 p a\alpha\kappa Z^2/a^2}{\lambda^2(Z^2/a^2+\kappa^2)^2}\right. \\
& \left.-\frac{8\pi^2 p}{\lambda^2(Z^2/a^2+\kappa^2)}\right\} + \sin^2\theta\cos^3\theta\cos^2\phi\left\{\frac{256\pi^3\kappa^3}{\lambda^3(Z^2/a^2+\kappa^2)^3}-\frac{96\pi^3\kappa}{\lambda^3(Z^2/a^2+\kappa^2)^2}\right\} \\
& +\frac{\pi^2 a^2}{Z^2\lambda^2}-\frac{\pi a\alpha p}{\lambda}\cos\theta+\frac{a^2\alpha^2 p^2}{4}\left(\frac{Z^2}{a^2}+\kappa^2\right)\cos^2\theta.
\end{aligned} \tag{137}$$

According to Sommerfeld and to the Eqs. (47)

$$\kappa = \frac{2\pi m v}{h(1-v^2/c^2)^{1/2}}; \quad a = \frac{h^2}{4\pi^2 m c^2} \quad (138)$$

$$\frac{Z^2}{a^2} + \kappa^2 = \frac{8\pi^2 m v}{h} \quad (139)$$

furthermore

$$p^2 \approx \epsilon/2mc^2 = (h\nu - I_0)/2mc^2 \quad (I_0 - \text{ionization potential}) \quad (140)$$

and

$$\pi a \alpha / \lambda = h\nu / 2mc^2. \quad (141)$$

If these values are substituted into Eq. (137) then

$$\begin{aligned} \phi\psi = & \sin^2 \theta \cos^2 \phi \left(1 + \frac{h\nu}{mc^2} - \frac{I_0}{2mc^2} \right) + \frac{2v}{c} \left(1 - \frac{\alpha^2 Z^2}{8} + \frac{v^2}{c^2} + \frac{h\nu}{4mc^2} \right. \\ & \left. - \frac{h\nu}{c^2 m v} \right) \sin^2 \theta \cos \theta \cos^2 \phi + \frac{3v^2}{c^2} \left(1 - \frac{h\nu}{3mv^2} \right) \sin^2 \theta \cos^2 \theta \cos^2 \phi \\ & + \frac{4v^3}{c^3} \left(1 - \frac{3h\nu}{4mv^2} \right) \sin^2 \theta \cos^3 \theta \cos^2 \phi + \frac{\pi^2 a^2}{Z^2 \lambda^2} - \frac{h\nu}{4mc^2} \cdot \frac{v}{c} \cos \theta \\ & + \frac{h\nu}{8mc^2} \frac{v^2}{c^2} \cos^2 \theta. \end{aligned} \quad (142)$$

The term $-\alpha^2 Z^2/4$ in the parenthesis after $3v^2/c^2$ was omitted, because other terms of the same order have been also omitted for the present approximation.

If the right side of the Eq. (142) is divided by $1 + h\nu/mc^2 - I_0/2mc^2$ then to the same degree of approximation

$$\begin{aligned} \phi\psi = & \sin^2 \theta \cos^2 \phi \left\{ 1 + \frac{2v}{c} \left(1 - \frac{\alpha^2 Z^2}{8} + \frac{I_0}{2mc^2} + \frac{v^2}{2c^2} - \frac{3h\nu}{4mc^2} - \frac{1}{2} \frac{h\nu}{cmv} \right) \cos \theta \right. \\ & \left. + \frac{3v^2}{c^2} \left(1 - \frac{h\nu}{3mv^2} \right) \cos^2 \theta + \frac{4v^3}{c^3} \left(1 - \frac{3h\nu}{4mv^2} \right) \cos^3 \theta \right\} \\ & + \frac{\pi^2 a^2}{Z^2 \lambda^2} - \frac{h\nu}{4mc^2} \frac{v}{c} \cos \theta + \frac{h\nu}{8mc^2} \frac{v^2}{c^2} \cos^2 \theta \end{aligned} \quad (143)$$

On the basis of Eq. (143) one can calculate, as Sommerfeld has done, the angle of the cone surrounding the z axis inside of which half of the electrons are emitted. Then to Sommerfeld's degree of approximation

$$\theta = \pi/2 - v/2c. \quad (144)$$

This result agrees with the elementary calculation of the basis of the quantum hypothesis.¹⁷ Sommerfeld's result differs by the factor 9/5 before

¹⁷ A. H. Compton, X-rays and Electrons, London, 1927, p. 240.

$-v/2c$ which is due, as can be seen by repeating his calculations, to the neglecting of the normalizing factors for the spherical harmonics. Thus, instead of the harmonics

$$P_k^m(\cos \theta) \quad (145)$$

in the formula (4) on the 210th page of the "Wellenmechanisches Ergänzungsband," the functions

$$\left[\frac{(k-m)!}{(k+m)!} \frac{2k+1}{2} \right]^{1/2} P_k^m(\cos \theta) \quad (146)$$

ought to be used, otherwise the formula (7) on the page 212 is not correct. The same remark applies to the result of Carrelli.

To calculate the angle θ with a higher degree of accuracy one can start from the equation given by Sommerfeld

$$\int_0^{2\pi} \int_0^\theta \phi \psi \sin \theta d\theta d\phi = \int_0^{2\pi} \int_0^\pi \phi \psi \sin \theta d\theta d\phi. \quad (147)$$

To simplify the notations the relation (143) can be written in the form

$$\phi \psi = \sin^2 \theta \cos^2 \theta (1 + b \cos \theta + c \cos^2 \theta + d \cos^3 \theta) + A - B \cos \theta + C \cos^2 \theta. \quad (148)$$

Eq. (147) leads then to

$$2 \cos \theta + 4A \cos \theta + b \cos^2 \theta - \frac{2 \cos^3 \theta}{3} = \frac{b}{2} + \frac{d}{6} - 2B. \quad (149)$$

If it is supposed that θ is equal to $\pi/2 - x$, then from (149) it follows that

$$\sin x = \frac{b}{4} + \frac{d}{12} - B - \frac{5b^3}{192} - \frac{Ab}{2} \quad (150)$$

whence, on account of (143)

$$\sin x = \frac{v}{2c} \left(1 - \frac{\alpha^2 Z^2}{8} + \frac{I_0}{2mc^2} + \frac{3v^2}{4c^2} - \frac{7h\nu}{4mc^2} - \frac{1}{2} \frac{h\nu}{cmv} - \frac{2\pi^2 a^2}{Z^2 \lambda^2} \right). \quad (151)$$

If it is supposed that the photoelectrons are emitted from the K-level only, which conforms with the initial assumptions in this paper then

$$\frac{I_0}{2mc^2} = \frac{RhZ^2}{2mc^2} = \frac{\alpha^2 Z^2}{4} \quad (152)$$

and so Eq. (151) can be written in the following form

$$\sin x = \frac{v}{2c} \left(1 - \frac{5\alpha^2 Z^2}{8} - \frac{h\nu}{4mc^2} - \frac{1}{2} \frac{h\nu}{cmv} - \frac{2\pi^2 a^2}{Z^2 \lambda^2} \right). \quad (153)$$

According to Birge¹⁸ $\alpha = 7.283 \times 10^{-3}$ and $h/mc = 0.02428\text{\AA}$. If moreover the value of λ is given in Ångström units, then finally

¹⁸ R. T. Birge, Phys. Rev. Suppl., July 1929.

$$\sin x = \frac{v}{2c} \left(1 - 3,53 \cdot 10^{-5} Z^2 - \frac{v}{4c} - \frac{0.006}{\lambda} - \frac{5.50}{Z^2 \lambda^2} \right). \quad (154)$$

Eq. (154) shows that the increase of the frequency of the incident radiation causes a decrease of $\sin x$ from the value $v/2c$. However, this effect becomes appreciable only for very high frequencies such as correspond to very hard x-rays, and γ -rays. This does not apply to the last term in the brackets, namely $5.50/Z^2 \lambda^2$, which becomes of importance even for ordinary x-rays in the case of low values of Z . Therefore for helium and especially for hydrogen the value of $\sin x$ should be markedly less than $v/2c$. For both these gases and for x-rays of the order of 1\AA the coefficient A in Eq. (149) becomes of the order of unity and so instead of Eq. (159) it follows that

$$\sin x = \frac{b}{4(1+2A)} \left\{ 1 + \frac{d}{36} - \frac{4B}{6} - \frac{b^2}{48} \frac{(5+12A)}{(1+2A)^3} \right\} \quad (155)$$

whence finally

$$\sin x = \frac{v}{2c(1+2A)} \left\{ 1 - 3.77 \times 10^{-5} Z^2 - \frac{v}{4c} - \frac{0.002}{\lambda} - \frac{v^2}{12c^2} \frac{5+12A}{(1+2A)^3} \right\} \quad (156)$$

where

$$A = \frac{\pi^2 a^2}{Z^2 \lambda^2} = \frac{2.75}{Z^2 \lambda^2}. \quad (157)$$

The formulas (154) and (156) do not agree with the results obtained recently by Williams, Nuttall and Barlow¹⁹ but they represent fairly well the results of other authors.²⁰ However, the experimental methods used to find the spatial distribution of photoelectrons cannot as yet claim a high degree of accuracy and it seems therefore well to wait for a final decision till more experimental data are available.

It is to be noted that the angle of the maximum emission of photoelectrons does not coincide with the above computed $\theta = \pi/2 - x$. This angle can be calculated from the formula

$$\frac{d}{d\theta}(\phi\psi) = 0. \quad (158)$$

In the first approximation this leads to the value

$$\theta_1 = \pi/2 - v/c \quad (159)$$

which differs from the corresponding value of Sommerfeld

$$\theta_1 = \pi/2 - 9v/5c \quad (159')$$

by the disappearance of the factor $9/5$.

¹⁹ E. J. Williams, *Nature*, **121**, 134 (1928). E. J. Williams, J. M. Nuttall and H. S. Barlow, *Proc. Roy. Soc.* **121**, 611 (1928).

²⁰ A. Sommerfeld, *l.c.* p. 225, fig. 20.

In the second approximation it can be found that according to Eqs. (158) and (148)

$$\theta_1 = \pi/2 - x_1$$

where

$$\sin x_1 = \frac{b}{2} + \frac{cb}{2} - \frac{5b^3}{16} - \frac{B/\cos^2 \phi}{2} \quad (160)$$

or according to Eqs. (148) and (143)

$$\sin x_1 = \frac{v}{c} \left\{ 1 - \frac{11h\nu}{4mc^2} + \frac{5\alpha^2 Z^2}{8} + \frac{1}{2} \frac{h\nu}{cmv} - \frac{h\nu}{8mc^2} \frac{1}{\cos^2 \phi} \right\}. \quad (161)$$

Hence finally by using the formerly given values of h/mc and α

$$\sin x_1 = \frac{v}{c} \left(1 + 3.53 \cdot 10^{-5} Z^2 - \frac{v}{4c} - \frac{0.067}{\lambda} - \frac{0.003}{\lambda \cos^2 \phi} \right). \quad (162)$$

It can be readily seen from this formula that for very hard x-rays the value of $\sin x_1$ begins to be appreciably smaller than v/c , but for the same values of v and λ the values of $\sin x_1$ increases with the increase of Z .

The independence of the maximum of photoelectric emission from the value of A can be readily understood with regard to the fact that Eq. (148), if coefficients B and C are neglected represents a superposition of an emission given by the term

$$\sin^2 \theta \cos^2 \phi (1 + b \cos \theta + c \cos^2 \theta + d \cos^3 \theta)$$

which shows a pronounced maximum and an emission independent from the direction in space, represented by the term A .

The values of the angles of maximum photoelectric emission which follow from the data of Loughridge²¹ agree fairly well with the formula (162). This formula ceases to be valid for ϕ nearly equal $\pi/2$ or $3\pi/2$.

The author wishes to express his gratitude to the International Education Board for the granting of a fellowship.

Note added during the proof. The average forward momentum of the photoelectrons can be calculated readily from the Eq. (148). It appears to be equal to $bmv/5$ or, if the ionization energy is neglected, so that

$$b = \frac{4h\nu}{c} / mv$$

equal to $0.8h\nu/c$. According to Williams (Proc. Roy. Soc. 121, 611, 1928) an average momentum $0.8h\nu/c$ of photoelectrons in the direction of the x-ray beam corresponds to a constant momentum $5/4$ ($0.8h\nu/c$) in the direction of the x-ray beam, superimposed on the radial momenta of the photo-

²¹ D. H. Loughridge, Phys. Rev. 30, 488 (1927).

electrons distributed proportionally to $\sin^2 \theta \cos^2 \phi$. It follows that this additional component of momentum is equal to the momentum of the photon.

It is to be noted that all the results of this paper were obtained by neglecting the term $-i\delta \log r$ in the exponential of the formula (56). The value of δ is according to Eq. (57)

$$\delta = \frac{\gamma^2}{2} \left(\frac{A}{B} + \frac{B}{A} \right) = \gamma^2 \frac{c}{v}. \quad (163)$$

The smaller the value of δ , the smaller the effect of its neglect. It follows that the results of this paper are more exact, the greater the velocity of the photoelectrons and the smaller the atomic number.

The calculations of this paper can be repeated taking δ into account, which causes the wave functions representing the photoelectrons to take the form

$$\psi \sim r^{-i\delta} e^{-i\kappa r} / r. \quad (164)$$

The calculations are easy but rather long; they lead to the result that to the first approximation

$$\phi\psi \sim \sin^2 \theta \cos^2 \phi \left\{ 1 + \frac{2v}{c} \left(1 + \frac{\delta Z}{2a\kappa} \right) \cos \theta \right\}. \quad (165)$$

It follows that for $\delta Z / 2a\kappa \ll 1$ or $(v/c)^2 \gg (\alpha Z)^3 / 2$ the terms with δ can be neglected and the formula (143) is then valid.

Thus for comparatively slow photoelectrons and high atomic numbers the formula (165) is to be applied instead of (143), whereas this latter formula is valid for high speed photoelectrons and low atomic numbers. Eq. (165) ceases to be valid for very slow photoelectrons, because the use of the asymptotic formula (164) is then not justified.

THE REFLECTION OF BEAMS OF THE ALKALI METALS FROM CRYSTALS

BY JOHN B. TAYLOR*

GENERAL ELECTRIC COMPANY, SCHENECTADY, N. Y.

(Received January 9, 1930)

ABSTRACT

Beams of lithium, potassium, and caesium were reflected from crystals of sodium chloride and lithium fluoride, as a means of studying the wave nature of these atoms. Incident angles from 2° to 60° were investigated. Although one one-hundredth percent of specular reflection could have been detected, no trace of such a reflection or of diffraction was found. The measured angular distribution of reflected atoms followed closely the cosine law. Apparatus, and the detecting device depending on positive ion emission by which this sensitivity of measurement was obtained, are described.

THE reflection of a beam of atoms from a crystal or ruled grating has for some time been recognized as a means of investigating the wave nature of the atoms.¹ Recently the author has described a method of detection and intensity measurement of molecular beams.² This method has proved so reliable and sensitive that it gave opportunity for a very detailed study of the reflection of the alkali metals from crystals. This has been done, using the detector for measuring the angular distribution of the atoms reflected when a beam of alkali metal atoms is allowed to fall upon a crystal.

Reflection experiments have already been carried out for a few atoms. Knauer and Stern³ have obtained specular reflection of helium and hydrogen molecules from sodium chloride and potassium chloride crystals. In addition they have measured distinct surface diffraction beams arising from the crossed grating. These occur, within the present limits of the experiment, at the angle calculated from the surface grating formula using the de Broglie wave-length, $\lambda = h/mv$, obtained from the velocity and mass of the helium atom. Johnson⁴ has shown that hydrogen atoms are specularly reflected from sodium chloride. Kirschbaum⁵ also reports experiments with hydrogen atoms. No evidence of diffraction was found in either case. Ellett, Olson, and Zahl⁶ have obtained specular reflection of cadmium, mercury, arsenic, and antimony from sodium chloride crystals. Certain features of their results not in

agreement with a surface grating action are yet to be explained. They also report a trial of reflection of sodium from sodium chloride. No regular reflection was observed.

In the present work, beams of lithium, potassium and caesium have been reflected from crystals of sodium chloride and lithium fluoride. The most probable de Broglie wave-lengths in question, at furnace temperatures of 900° , 500° , and 450°K respectively, vary from about 0.2×10^{-8} cm for lithium to 0.07×10^{-8} cm for caesium. No trace of specular reflection or diffraction has been found. On the contrary the intensity of reflection measured at various angles with the surface follows almost exactly the cosine law of Knudsen; i.e. all of the atoms are reflected diffusely from the point of incidence. One-tenth of one percent specular reflection could easily have been observed in the

Fig. 1. Section of apparatus showing path of beam to crystal and detector.

present experiments. In some cases one one-hundredth of a percent could have been detected. In the other experiments mentioned the specular reflection has varied from almost one hundred percent⁷ in the case of helium, to 10 to 20 percent in the case of cadmium, and one or two percent for atomic hydrogen.

APPARATUS

The beam forming arrangement, furnace, slits, etc. are practically the same as have been described previously.⁸ Figure 1 gives a schematic view

⁷ Recent experiments of O. Stern about to be published, and as described to the author in private communication.

⁸ J. B. Taylor, *Zeits. f. Physik* 52, 846 (1929); 57, 242 (1929).

of the situation. Atoms of the alkali metal evaporate through a fine slit in the steel oven (1) which is heated by radiation or by electron bombardment from the tungsten spiral (2). The beam is then formed by a second slit (3) and passes into the reflection chamber (4). Here it impinges on the crystal surface (5). The reflected atoms are received on the filament of the detector (6) which can be moved to intercept and measure the number of atoms leaving the crystal at any angle.

In the sketch the detector in position (4) observes the specular beam. The detector was a platinum cylinder eighteen \times fifty mm with a coaxial pure tungsten filament 0.05 mm in diameter. The cylinder was held ten volts negative to the filament and at a temperature of about 1500°K. Every alkali metal atom striking the filament leaves as a positive ion.⁹ Thus the positive ion current is at once a measure of the intensity of the beam or of the reflected atoms at the point. The detector is carried on the ground joint (7) Fig. 2, by

Fig. 2. End view of detecting chamber showing mounting and motions of crystal and detector.

which it may be moved to cover various angles of reflection. For lithium the detector filament was oxygen on tungsten.

The oven and crystal chambers were evacuated separately by two large Langmuir pumps. Liquid air traps (8), (9), (10), served to protect the chambers from grease vapors from the joints. The walls of the apparatus were held below room temperature by the water jacket (11). Added protection is given the detector and crystal by a sheet copper shield (12) cooled by liquid air from the trap (10). (13) is a shutter operated by action of a small magnet on an iron lever. It allowed interruption of the beam at any instant.

The crystal (5) is carried in the holder and heater (14). A tungsten spiral running through the body of the holder allows heating the crystal by radiation to at least 500°C. The holder is mounted on the ground joints (15) and (16) Fig. 2. (15) is eccentric in (16) so that by turning (16) the crystal can be

⁹ I. Langmuir and K. H. Kingdon, *Proc. Roy. Soc.* **21**, 380 (1923).

raised into or lowered out of the path of the beam. By turning (15) the crystal is rotated on an axis through its surface and coaxial with the motion of the detector, to set the crystal at any incident angle with the beam.

Since the detector motion is coaxial with the crystal motion, the filament remains equidistant from the crystal at all angles and the positive ion currents require no correction for distance.

Graduations on the various joints permitted accurate readings of the angular settings.

Crystals used. Natural crystals of sodium chloride were used in a few experiments. Later to secure more perfect crystals, they were grown from the melt by the excellent method of Kyropolous.¹⁰ Single crystals 3 to 5 cm in diameter were easily made in a few hours. Lithium fluoride was first purified by this method from an impure melt, and then crystalized from a melt of the pure product. The crystals were held at 2 to 300°K until ready for use. After cleaving they were immediately inserted in the apparatus and evacuation and heating begun at once.

During the reflection experiments the crystals were held at temperatures varying from room temperature to about 500°C. The elevated temperatures were to prevent if possible the momentary condensation or adsorption of alkali metal atoms on the crystal surface, and to insure a surface free from adsorbed gases.

The crystals used were 5 to 10 mm × 6 mm.

PROCEDURE

The oven was loaded and the experiment begun as described⁸ previously, with the addition of the crystal introduction. After five to eight hours pumping and heating of the crystal the oven was brought gradually to a temperature giving the desired beam intensity. This changing oven pressure could be readily followed by moving the detector into the path of the beam, (position *B* in Fig. 1), with the crystal lowered. In addition when the desired intensity was reached the detector filament was moved by 0.01 to 0.05 mm steps through the beam to measure its intensity from point to point. Thus in size and intensity the incident beam was accurately known. Fig. 3 gives examples of such measurements. The small displacements of the filament during this measurement were controlled by use of a traveling microscope with eyepiece micrometer. Through the glass window (17) and the detector opening (18), the filament could be seen as a bright line against the scale.

The width of the beams striking the crystal was changed in different trials from 0.05 mm to 1 mm. The maximum intensity in the undeflected beam at *B* was varied from 30 cm full galvanometer sensitivity to about 60 meters equivalent deflection. These latter were measured with galvanometer shunted to one-thirtieth of full sensitivity. The galvanometer had a full sensitivity of 4×10^{-11} amps. per mm.

Then by means of the joint (16) the crystal was raised into and parallel to the beam. This could be done very accurately by noting the decrease in gal-

¹⁰ S. Kryopolous. *Zeits. f. Anorg. Chemie* **154**, 308 (1926).

vanometer deflection as the crystal intercepted half of the beam. Next with the shutter (13) closed the crystal was turned to whatever incident angle desired, the shutter opened and observations begun. Incident angles from 2° to 60° were investigated. By joint (7) the detector was moved around the crystal, the intensity of the reflected atoms at any angle being recorded immediately by a certain steady galvanometer deflection. In the neighborhood of the expected specular reflection the steps could be made in fractions of a degree and the whole region explored a number of times to remove any question as to the character of the reflection. Readings could also be made by setting the detector at a given angle and then rotating the crystal to investigate any preferred angles of reflection.

Fig. 3. Examples of intensity measurements of beams used. Solid lines are the geometrical beams constructed from the slit arrangements.

At any angle of reflection, if the shutter was closed the galvanometer deflection fell at once to zero.

At any time the crystal could be lowered and a check made on the constancy of the incident beam.

At the larger beam intensities one-tenth percent of specular reflection would have given 30 to 60 mm galvanometer deflection. However in no case was there the slightest indication of specular reflection.

Fig. 4 shows a reflection measurement with potassium from sodium chloride at an incident angle of 15° . The reflection from lithium fluoride and at other intensities of the main beam gave similar data.

An interesting critical temperature phenomenon was noted in the course of the experiments. If the crystal was allowed to cool, a temperature range was reached where the reflection at any angle fell very quickly practically to zero. This temperature where almost all the incident atoms were condensing on the crystal varied, as to be expected, with the incident beam intensity. It

is apparent that the combination of beam and detector offers a precise method of studying surface condensation and evaporation phenomena.

The experiments made so far on the reflections of atoms from crystals have led to no explanation of the efficiency of reflection. The great ease with which the alkali metal atoms are adsorbed on surfaces is believed to explain at least in part their failure to be specularly reflected or diffracted. To avoid this, the possibility is suggested of employing crystals which may be heated to

Fig. 4. Showing measured angular distribution of reflection (points) as compared to a cosine distribution (solid curve); the incident beam making an angle of 15° with crystal. Cross indicates intensity which would have been measured at 15° if one-tenth percent of the incident atoms had been specularly reflected.

still higher temperatures than in these experiments, or crystals on which the adsorbing forces are much smaller. However unless unusual conditions as to reflecting surface can be secured, it may not be possible to detect an appreciable specular reflection of the alkali metal atoms.

The writer wishes to express his appreciation of support from the National Research Council and to Professor G. N. Lewis for the facilities so kindly made available at the University of California.

THE EMISSION OF POSITIVE IONS FROM
TUNGSTEN AND MOLYBDENUM

BY LLOYD P. SMITH

DEPARTMENT OF PHYSICS, CORNELL UNIVERSITY

(Received November 25, 1929)

ABSTRACT

An examination of the positive ion emission from tungsten and molybdenum has been made in which it was sought to determine the following points: (1) The nature of the ions emitted at various temperatures; (2) the temperature variation of the positive ion current; (3) the theory of positive ion emission with regard to where and how the ions are formed; (4) the positive ion work function for these metals; (5) whether the work function, determined by experiment, checks with that calculated by a simple cyclic process involving the thermionic work function, the ionizing potential, and the latent heat of evaporation of the metal.

The mass spectrum for tungsten and molybdenum filaments taken at moderate temperatures (1700° to 2000°K) has shown that the emitted ions consist of sodium, the two isotopes of potassium, and aluminum. At high temperatures these impurities disappear and finally both tungsten and molybdenum filaments yield positive ions of their own metal. The latter confirm a report by Wahlin. The temperature variation of the positive ion current at high temperature yields a value of 6.55 volts for the positive ion work function of tungsten and 6.09 volts for that of molybdenum. These values disagree widely from the values 10.88 volts and 9.26 volts calculated from the simple cyclic process mentioned above. This suggests that the ions are formed as a by-product of an irreversible recrystallization of the metal. Theoretical considerations show that the ions are emitted from the metal and are not formed after a neutral atom evaporates.

UNTIL recently, it has been thought that any positive ion emission from metals was due entirely to ionized atoms of one or more impurities which existed in the metal. O. W. Richardson¹ has shown that most metals contain a very small amount of potassium which is driven out of the metal as the temperature is raised. He obtained rather erratic results from tungsten and did not give any data concerning molybdenum. His work was carried on for temperatures below 2,000°K. J. J. Thomson² investigated the positive ion emission from platinum by crossed electric and magnetic fields and found in addition to those of alkaline impurities, ions having an atomic weight of 27 which he concluded were ionized CO molecules. More recent work³ has shown definitely that platinum contains potassium and sodium as impurities which are ionized and emitted at high temperatures.

During the summer of 1927 the author attempted to perfect a plotron having a grid extremely well insulated. It was found during the course of this investigation that part of the electric leakage to the grid was due to positive

ions arising at the filament. These ions persisted even after the filament was flashed to some $3,000^\circ$ and then well aged. An investigation of the nature of these high temperature ions and the variation of the positive ion current with temperature was undertaken. After the work was begun it was noted that Jenkins⁴ had found that the tungsten cathode of a Coolidge x-ray tube was a source of positive ions. Mitra⁵ carried on the investigation and obtained data on the temperature variation of the positive ion current using a commercial type of radio tube having a tungsten filament, but did not attempt to determine the positive ion work function. The author has given a preliminary report⁶ on such a work function.

MASS SPECTROGRAPH

The apparatus for obtaining the mass spectrum of the ions is shown diagrammatically in Fig. 1. It consisted essentially of a copper tube *A* in the form of a half torus ring spun from sheet copper. The diameter of the cross section was approximately 2.5 cm. Caps having the slits *S*₁ and *S*₂ were placed over the ends. The slit *S*₁ was about 0.8 mm wide and 8 mm long. The slit

Fig. 1. Diagram of mass spectrograph.

*S*₂ was somewhat larger being about 3 mm wide and 1 cm long. A wire filament of the metal under investigation having a length of about 1.4 cm was placed at *F*, parallel to the slit *S*₁ and about 5 mm away from it. Ions passing through *S*₁ and bent by the magnetic field on an arc whose radius was 6.95 cm were focused at *S*₂. Those passing through *S*₂ were collected on the electrode *C* which was connected to a quadrant electrometer. The accelerating potential was applied between *D* and *F*. The copper tube together with the filament leads and collector leads were all sealed into a glass tube *B* which was exhausted at *E*. A pressure less than 10^{-6} cm of Hg was maintained. The tube was placed between poles of an electromagnet having pole pieces of large diameter. The field in the region occupied by the tube was found to be uniform and its intensity was determined by careful flip coil measurements.

In determining the mass spectrum, the field intensity was set at a given value and the accelerating potential was varied very slowly but continuously

⁴ Jenkins, *Phil. Mag.* **47**, 1025 (1924).

⁵ Mitra, *Phil. Mag.* **5**, 67 (1928).

⁶ Smith, *Phys. Rev.* **33**, 279 (1929).

by a mechanical device. The presence of a particular ion was noted by a drift of the electrometer. When it began to drift, the rate of drift for various accelerating potentials was taken and from these data the voltage yielding the maximum rate of drift was obtained. The voltage across the filament was measured and one half of this drop was added to the voltage producing maximum drift to yield the true accelerating potential.

NATURE OF THE IONS

From the accelerating potential corresponding to a given electrometer current, the atomic weight W was computed by means of the expression $W = (1/V) [RH/144.5]^2$ where R is the radius of the path traversed in cm, H is the field intensity in gauss, and V is the accelerating potential in volts. The electrometer current in arbitrary units was plotted against W to give a mass spectrogram. A typical mass spectrum for tungsten at moderate temperature is shown in Fig. 2. The peak at $W = 23.1$ is due to sodium ($W = 23.0$) and could

Fig. 2. Mass spectrum from tungsten at moderate temperatures (1600–2000°K).

be detected at a temperature of about 1700°. The peaks at $W = 39$ and 41.1 were also present at this temperature. They are undoubtedly due to the two isotopes of potassium occurring at $W = 39$ and 41 . The only element falling in this region is calcium ($W = 40.07$). No evidence of calcium ions has been found and in fact it would be quite improbable that any appreciable amount of calcium would be ionized at these temperatures for its ionization potential is too high (6.09 volts). The peak occurring at $W = 27.2$ did not show up until temperatures over about 2,000° were reached. This atomic weight compares well with aluminum ($W = 27.0$), and since the ionizing potential of aluminum is 5.9 volts we would not expect to find it until a higher temperature is reached than would yield either potassium or sodium ions whose ionizing potentials are 4.3 and 5.1 volts respectively. As mentioned before, J. J. Thomson found ions of atomic weight 27 emitted from platinum and concluded that they were ions of CO molecules ($W = 28$). It seems improbable that these were really positively ionized CO molecules because the ionizing potential of such molecules is of the order of 14 volts, much too high to have any ions of CO present

below the melting point of platinum. It therefore seems extremely likely that aluminum was present as an impurity.

Fig. 3 is the mass spectrum obtained from molybdenum. It shows the presence of the same impurities as existed in the tungsten. This spectrum does not show as high a resolution as the one for tungsten but this is doubtless due to the fact that it was obtained at a higher temperature and the voltage drop along the filament broadened the peaks. It is interesting to note that

Fig. 3. Mass spectrum from molybdenum at moderate temperatures.

these impurities are present in extremely small amounts. A spectroscopic analysis was made on the samples of tungsten and no trace of the impurities here detected was found, which indicates that each was probably present in an amount less than 1 part in 100,000 and certainly less than 1 part in 10,000.

These ions which are emitted at moderate temperatures become less in number as time of heating increases and they can be gotten rid of quite

Fig. 4. Mass spectrum of molybdenum and tungsten at high temperatures.

rapidly if the filament is aged at higher temperatures. As the temperature is increased a point is found where no ions of impurities are emitted. On further increasing the temperature to about 2500° for tungsten and 2300° for molybdenum new ions are emitted. The spectrum curves for molybdenum and tungsten at these temperatures are plotted in Fig. 4. These spectra leave no doubt that the high temperature ions from tungsten found by Jenkins and the author are really tungsten ions, and that molybdenum also emits positive ions

of molybdenum. While this paper was being prepared Wahlin reported in a brief note⁷ that he had found tungsten, molybdenum, tantalum, and rhodium to emit positive ions of their own metal. The results given here corroborate his results for tungsten and molybdenum.

No trace of doubly ionized atoms was found nor was there any evidence of ions which were singly charged but having a mass of two or more atoms of the material, although they were looked for. It appears that the ion of the metal is emitted as a singly ionized atom.

VARIATION OF EMISSION WITH TEMPERATURE

To obtain the magnitude of the positive ion current for a given temperature, the form of tube shown in Fig. 5 was used. The current to the lower cylinder was measured. For tungsten, the temperature was determined from the current through a given sized filament as given by Langmuir and Jones.⁸

Fig. 5. Tube used to measure the positive ion current.

For molybdenum the temperature was determined from data kindly supplied by S. Dushman giving the watts per cm^2 as a function of the temperature. Volt-ampere characteristics of two hair pin filaments were taken. They had the same diameter but different lengths, and were electrically welded to identical lead wires. By a method of differences the cooling effect of the leads was eliminated and the temperature of the center of the longer filament was obtained as a function of the current through it.

The magnitude of the positive ion current from tungsten at a given temperature depends on the heat treatment through which the filament has passed. Furthermore there exists a decay with time which is slow after the filament has been allowed to age for a time and has been carried over the range

TABLE I. *Variation of positive ion current with temperature.*

Tungsten		Molybdenum

⁷ Wahlin, Phys. Rev. **34**, 164 (1929).

⁸ Langmuir and Jones, General Electric Rev. p. 510, June 1927.

of temperatures to be used. Hence in the case of tungsten no final value of the current at a given temperature can be given. After a few hours aging at about 2300°, molybdenum seemed to give values that were reproducible. These values could be duplicated after aging for several hours more at 2300°. Table I shows data for tungsten and molybdenum obtained after some 5 hours aging.

POSITIVE ION "WORK FUNCTION"

In determining electronic work functions it has been customary to make use of the usual electron emission formula

$$I = AT^2 e^{-(\phi_- e/kT)}.$$

The work function ϕ_- is found by plotting $\log I - 2 \log T$ against $1/T$ and determining the slope of the straight line thus found. This procedure however would be incorrect for determining the work function for positive ions because of the difference in the process involved in the evaporation of ions. We shall therefore deduce an expression which should be applicable for the evaporation of ions.

Following Bridgman⁹ we take a neutral metal composed of n atoms at 0° absolute and raise its temperature to T and evaporate m ions reversibly at the equilibrium pressure. At this temperature we then have a positive ion gas, a negative surface charge, and the remaining neutral metal. Let the entropy of one atom in the condensed state be denoted by s_1 , the entropy of one evaporated ion by s_2 and the entropy to be associated with the heat of surface charging produced by the evaporation of one ion by s_2' . The entropy before evaporation is then ns_1 and the entropy after the evaporation of m ions is $ms_2 + ms_2' + (n-m)s_1$. Since the entropy after evaporation minus the entropy before evaporation must equal the change of entropy during evaporation we have,

$$(mL/T) = m(s_2 + s_2') + (n-m)s_1 - ns_1$$

where L is the latent heat of evaporation of one ion, the metal being isolated. This expression reduces to

$$(L/T) = s_2 + s_2' - s_1. \quad (1)$$

Using essentially the same expressions for s_1 , s_2 and s_2' as Bridgman, Eq. (1) becomes—

$$\begin{aligned} \frac{L}{T} = k \left[\frac{5}{2} + \log_e \frac{(2\pi M)^{3/2} k^{5/2}}{h^3} + \frac{5}{2} \log_e T - \log_e P \right] \\ + \int_0^T \frac{C_{pp}}{T} dT - \int_0^T \frac{C_{pm}}{T} dT + s_p \end{aligned} \quad (2)$$

where p is the equilibrium vapor pressure of the ion gas; M is the mass of one ion; C_{pm} is the heat capacity, at constant pressure, of an ion in the condensed

⁹ Bridgman, Phys. Rev. 27, 173 (1926).

state; $C_{p\rho}$ is the heat capacity associated with the surface heat of charging produced by the evaporation of one ion, and s_ρ is the entropy associated with the surface heat of charging at $T=0$.

The latent heat of evaporation may be expressed as a function of the temperature by the relation⁹

$$L_T = L_0 + (5/2) kT + \int_0^T C_{p\rho} dT - \int_0^T C_{pm} dT \quad (3)$$

Combining Eqs. (2) and (3) we have:

$$\log_e p = -\frac{L_0}{kT} + \frac{5}{2} \log_e T + \log_e \frac{(2\pi M)^{3/2} k^{5/2}}{h^3} + \frac{s_\rho}{k} + \frac{1}{k} \left[\int_0^T \frac{C_{p\rho}}{T} dT - \frac{1}{T} \int_0^T C_{p\rho} dT \right] - \frac{1}{k} \left[\int_0^T \frac{C_{pm}}{T} dT - \frac{1}{T} \int_0^T C_{pm} dT \right].$$

This reduces to

$$\log_e p = -\frac{L_0}{kT} + \frac{5}{2} \log_e T + \log_e \frac{(2\pi M)^{3/2} k^{5/2}}{h^3} + \frac{1}{k} \int_0^T \frac{dT}{T^2} \int_0^T C_{p\rho} dT + \frac{s_\rho}{k} - \frac{1}{k} \int_0^T \frac{dT}{T^2} \int_0^T C_{pm} dT. \quad (4)$$

Under equilibrium conditions just as many ions condense as are evaporated per second, hence we may take the rate at which ions strike the surface of the metal at the equilibrium pressure as the rate of evaporation. It may be shown that at the pressure p the number of ions striking unit area per sec is

$$n = p / (2\pi M k T)^{1/2}$$

where M is the mass of the atom concerned. If some of the ions striking the metal are not condensed but are reflected then the number emitted must be $n = (1-r)p / (2\pi M k T)^{1/2}$ where r is a reflection coefficient. The positive ion current will be given by

$$I = ne = \frac{pe(1-r)}{(2\pi M k T)^{1/2}}$$

or

$$\log_e p = \log I + \frac{1}{2} \log_e 2\pi M k T - \log_e e - \log (1-r). \quad (5)$$

Making use of (5), Eq. (4) becomes:

$$\log_e I = -\frac{L_0}{kT} + 2 \log_e T + \log_e M + \log_e 2\pi k + \log_e \frac{k}{h^3} + \log_e e + \log_e (1-r) + \frac{1}{k} \int_0^T \frac{dT}{T^2} \int_0^T C_{p\rho} dT + \frac{s_\rho}{k} - \frac{1}{k} \int_0^T \frac{dT}{T^2} \int_0^T C_{pm} dT$$

or

$$\log_e I = -\frac{L_0}{kT} + 2 \log_e T + \log_e M + \log_e \frac{2\pi k^2 e}{h^3} + \log_e (1-r) \\ + \frac{1}{k} \int_0^T \frac{dT}{T^2} \int_0^T C_{pp} dT + \frac{s_p}{k} - \frac{1}{k} \int_0^T \frac{dT}{T^2} \int_0^T C_{pm} dT. \quad (6)$$

The integral containing C_{pm} has been evaluated¹⁰ for tungsten and molybdenum. Making use of the evaluation for tungsten and changing to logarithms to the base ten, Eq. (6) becomes

$$\log_{10} I + 0.363 \log_{10} T + 1.64 \times 10^{-4} T = \frac{-\phi_{+0}e}{2.303kT} + \frac{1}{2.303k} \int_0^T \frac{dT}{T^2} \int_0^T C_{pp} dT \\ + \frac{s_p}{2.303k} + \log_{10} (1-r) + 12.43. \quad (7)$$

Where $\phi_{+0} = L_0/e$ is the equivalent difference of potential through which an ion must be moved. The corresponding equation for molybdenum is,

$$\log_{10} I + 0.453 \log_{10} T + 2.70 \times 10^{-4} T = \frac{-\phi_{+0}e}{2.303kT} + \frac{1}{2.303k} \int_0^T \frac{dT}{T^2} \int_0^T C_{pp} dT \\ + \frac{s_p}{2.303k} + \log_{10} (1-r) + 12.76. \quad (8)$$

If it were known how C_{pp} varied with the temperature then the above equation would show exactly how the positive ion current varies with the temperature and the work function ϕ_{+0} could be found by putting all functions of T on the left hand side of the equation except the term containing ϕ_{+0} and plotting it against $1/T$. The slope of the straight line so obtained would yield ϕ_{+0} .

Langmuir and Tonks¹¹ have shown that the surface heat of charging for the removal of electrons from a surface is very small i.e., of the order of 0.04 volts, at 2270°. Although the fact that it is small does not mean that it cannot vary rapidly with the temperature, we shall for the present assume $C_{pp} = 0$.

Fig. 6 shows the result of plotting the data for tungsten according to Eq. (7). Curve I is that obtained by plotting the data for tungsten given in Table I. The points lie very close to a straight line. Curve II was obtained after a sample of tungsten had aged some 30 hours and the rate of decay of the positive ion current had become very small. The point to be noticed is that even though a decay has taken place and the positive ion current has become smaller for a given temperature it has the same temperature variation as it had for considerably less aging, for the slopes of the lines I and II are the same. Curve III shows the result of plotting the data given by Mitra according to Eq. (7). As is evident, the curve so obtained has a slope almost identi-

¹⁰ Jones, Langmuir and Mackay, Phys. Rev. 30, 201 (1927).

¹¹ Langmuir and Tonks, Phys. Rev. 29, 524 (1927).

cal to that of Curves I and II. The fact that it is displaced relative to the other lines does not yield any definite information because the area of emission used by him was not given. Since the slopes of these curves are the same the work function ϕ_{+0} is definitely determined. Eq. (7) represents each of the Curves I and II with suitable change in the constant term. A discussion concerning the value of the constant term will be given later.

As stated before, molybdenum after suitable aging gave reproducible results. The data given for Mo in Table I were plotted according to Eq. (8). Fig. 7 shows how well these data give a straight line thus determining a value for ϕ_{+0} for Mo.

Fig. 6. Curves for determining the positive ion work function of tungsten.

Fig. 7. Work function curve for molybdenum.

From Curve I, Fig. 6, ϕ_{+0} for tungsten is 6.55 volts, ϕ_{+0} determined from Curve II is 6.60 volts and from Mitra's data $\phi_{+0} = 6.55$ volts. It cannot be inferred that ϕ_{+0} is determined with an accuracy suggested by these figures for a slightly different line through the points yields a considerably different ϕ_{+0} as regards the third place, but 6.55 volts is undoubtedly a good representative value. The curve for molybdenum gives $\phi_{+0} = 6.09$ volts.

The constant term that must appear in Eq. (7) to represent the data plotted in Curve I, Fig. 6, is 6.51. If Curve II is considered to have the same slope as Curve I then the constant term for it is 6.28. From the curve for Mo it is found that the constant term of Eq. (8) must be 6.90.

Two serious difficulties now present themselves. The first is in regard to the constant terms just determined. Each of them is respectively much smaller than the numerical term appearing on the right side of Eqs. (7) and (8). On the assumption that the entropy associated with the surface heat of charging is zero, the constant 12.43 in Eq. (7) must be reduced to the value obtained (about 6.5) solely by the magnitude of the reflection coefficient r . To yield the proper constant, r would have to be so great that only 1 ion out of about 100,000 striking unit area would be condensed. It appears, however, that there is no quantitative evidence for such high values of r . For the evaporation of atoms, it has been found that satisfactory results are obtained when r has been assumed to be equal to or nearly zero, and even in thermionic emission r is probably not greater in order of magnitude than 0.5. Even if it had not been assumed that the entropy associated with the surface charge was zero, it is not likely that it would contribute a negative entropy constant term in Eqs. (7) and (8). Such a negative entropy would mean that heat would be developed when the metal surface became negatively charged and seems improbable. In fact evidence is presented later to indicate that heat is absorbed in the process of charging a metallic surface negatively.

The second difficulty seems more serious than the first. If we consider an inclosure in which molybdenum say is in equilibrium with its radiation at a given temperature T we may carry out the following cycle. Remove an electron and positive ion from the metal thus requiring an amount of work $\phi_{-T} + \phi_{+T}$ where ϕ_{-T} and ϕ_{+T} are the respective work functions at the temperature T , then allow the electron and ion to recombine thus producing a neutral atom and yielding an amount of energy corresponding to its ionizing potential V . Then let the atom condense on the metal thus yielding the heat of condensation. This is a reversible cycle and the sum of all the energy transfers should vanish thus:

$$\phi_{+T} + \phi_{-T} = V + U_T \quad (9)$$

where U_T is the heat of evaporation at the temperature T . Güntherschulze¹² has made use of such a cycle to compute ϕ_{+0} for those elements where the remaining data were available. With the ϕ_{+0} determined as above for molybdenum, all the terms of the cycle are known. U_T has been determined by Langmuir and Tonks,¹¹ V has been determined from the spectral series for molybdenum.¹³ At zero degrees, $\phi_{-0} = 4.42$ volts, $V = 7.35$ volts, $U_0 = 6.33$ volts. We note then that

$$V + U_0 = 7.35 + 6.33 = 13.68$$

$$\phi_{+0} + \phi_{-0} = 6.09 + 4.42 = 10.51$$

and that the cycle (9) *fails to close* by some 3.17 volts. Although the ionization potential for tungsten has not been determined it can be estimated as about 7.1 volts, and $U_0 = 8.31$ volts while $\phi_{-0} = 4.53$. For tungsten we have

¹² Güntherschulze, Zeits. f. Physik 31, 507 (1925).

¹³ Compton and Mohler, Nat. Res. Council Bulletin No. 48, 81.

$$V + U_0 = 7.1 + 8.31 = 15.41$$

$$\phi_{+0} + \phi_{-0} = 6.55 + 4.53 = 11.08.$$

Again the cycle does not close by some 4.33 volts.

Since the value of ϕ_{+0} which has been determined depends so greatly on the theoretical equation used, and the effect of a possible surface heat of charging and its variation with temperature, a check was made by computing the values occurring in Eq. (9) at a given temperature. In order to do this the Clausius-Clapeyron equation,

$$L_T = T(V - v_0)(dp/dT) \quad (10)$$

was used, where L_T is the heat of evaporation at the temperature T , V the volume of the vapor, v_0 the volume of the metal and p is the vapor pressure. Neglecting v_0 and setting $V = kT/p$ we have

$$L_T = \frac{kT^2}{p} \frac{dp}{dT} = kT^2 \frac{d(\log_e p)}{dT}. \quad (11)$$

We may express p in terms of the positive ion current by the relation (5), obtaining:

$$\log p = \log \left\{ \frac{\beta}{1-r} IT^{1/2} \right\} \quad (12)$$

where β is a constant. If r does not depend on T then Eq. (11) becomes:

$$L_T = kT^2 \frac{d}{dT} (\log_e IT^{1/2}).$$

This gives L_T in terms of the positive ion current measured and the temperature, and does not depend on any assumptions made concerning the surface heat of charging. Changing to logarithms to the base 10 and expressing L_T in terms of volts we have:

$$\phi_{+T} = 1.987 \times 10^{-4} T^2 \frac{d}{dT} (\log_{10} IT^{1/2}). \quad (13)$$

The values of $\log_{10} IT^{1/2}$ were plotted against T for molybdenum and the slope of this curve was determined at 2350°K. Using this slope, ϕ_{+} at 2350° was found to be 5.43 volts.

The electron work function ϕ_{-} at 2350° was computed from Eq. (3) assuming that the specific heat of the electrons in the condensed state was zero. Its value was found to be 4.92 volts. The value of U at 2350° was also computed by means of Eq. (3) in which the integral, $\int_0^T C_{pm} dT$ for Mo was obtained from the work of Jones, Langmuir, and Mackay.¹⁰ At $T = 2350^\circ$, U was found to be 5.41 volts. It is readily seen that if these values are substituted in the cycle (9) it still *fails to close* by some 2.45 volts. The failure of the cycle to close is, therefore, not due principally to our lack of knowledge concerning the surface heat of charging.

Under the assumption that C_{pp} equals zero Eq. (3) assumes the form

$$L_T = L_0 + \frac{5}{2}kT - \int_0^T C_{pm}dT. \quad (14)$$

The value of $\int_0^T C_{pm}dT$ for Mo was determined as stated above. Converting L_T to volts, Eq. (14) becomes,

$$\phi_{+T} = \phi_{+0} - 2.71 \times 10^{-4}T - 5.37 \times 10^{-8}T^2 + 0.019. \quad (15)$$

If C_{pp} is really zero then Eq. (15) should yield the same value of ϕ_{+} at 2350° as Eq. (13). Using the value of ϕ_{+0} already determined (6.09), ϕ_{+T} from Eq. (15) at 2350° is 5.17 volts as compared with 5.43 volts determined from Eq. (13). The difference between these two values represents a contribution due to surface charging, thus indicating that heat is absorbed in the process. By combining Eqs. (13) and (3) it would be possible to determine an empirical value for the $\int_0^T C_{pp}dT$ which in turn would modify the equation used to determine ϕ_{+0} and therefore yield a slightly different value for ϕ_{+0} . It does not seem desirable to do this until the theoretical form of C_{pp} is determined because the empirical relation could be expressed in several different forms which have no obvious theoretical significance.

It should be noted that ϕ_{+T} as expressed in Eq. (13) is independent of the reflection coefficient as a result of the *assumption* that r was independent of T . It is not at all unreasonable to suppose that r varies somewhat with the temperature but it would have to vary with *extreme* rapidity to yield a value of ϕ_{+0} which would satisfy the energy cycle (9). Such an extreme variation in r is not found in the evaporation of neutral atoms or electrons and therefore may be regarded as untenable in the case of ionic evaporation. It is therefore apparent that in Eqs. (7) and (8) there are no terms missing which change violently with the temperature and thus yield a value of ϕ_{+0} sufficiently large to close the energy cycle (9).

POSSIBLE EFFECTS OF THE FILAMENT SURFACE

It is well known that the condition of the filament surface affects the electron emission very greatly. The ordinary thermionic work function of a filament can be varied within wide limits by allowing a monatomic layer of foreign atoms to deposit on its surface. Such a layer of thorium on tungsten reduces the work function from 4.53 volts to 2.69 volts. On the other hand a layer of oxygen on tungsten increases it to 9.2 volts. Since the positive ion work function is related to the electron work function by Eq. (9) it follows that impurities on the surface would effect the positive ion work function materially. It could be supposed for example that the positive ions were really coming from small patches of the filament which were coated with oxygen atoms. For a tungsten filament coated with oxygen $\phi_{-0} = 9.22$ volts. Using this value of ϕ_{-} in Eq. (9), ϕ_{+0} comes out to be 6.2 volts which agrees fairly well with the value 6.55 volts determined by experiment.

If surface contamination is the cause of the discrepancy between the work function determined experimentally and that calculated from the cycle, it

is difficult to see how it could be due to oxygen. In the first place, as far as the writer is aware, it is impossible to keep oxygen atoms on the surface of tungsten at temperatures above 2300° or 2400°. In order to be sure that oxygen was not playing any part in the positive ion emission, a small amount of oxygen was admitted while the tungsten was emitting positive ions but the ion current was not affected until sufficient oxygen was admitted sensibly to cool the filament. A small amount of argon was admitted in the same way but the only effect was to decrease the ion current if an excessive amount was admitted. Argon is chemically inactive and its only action was probably a cooling of the filament.

It might be supposed that the surface of the filament was rough and jagged when looked at through a microscope and that the ions were being emitted from these microscopic points in the same way as electrons are emitted from cold metals. In the latter phenomenon, however, the electrons are emitted from the points because the field strength is extremely high at the point. In the case of positive ions however the voltage applied between the collector and filament was never greater than 150 volts and Mitra has shown that the ion current saturates very well thus making the correction for the Schottky effect very small. Furthermore tungsten undergoes a recrystallization at about 2800°K and filaments that have been made rough by ion bombardment can be made smooth again by raising the temperature above 2800°K. No extraordinary behavior of the ion current was noted in the neighborhood of this temperature.

RECOMBINATION AT THE FILAMENT SURFACE

If an appreciable amount of recombination took place at the surface of the filament, then it would be possible that the positive ion current as measured would not correspond to the actual rate of emission. The rate of recombination would be a function of the temperature and would modify the ion current in such a way that the measured ion current would not yield the true work function. The order of magnitude of this rate can be calculated from the Thomson theory of recombination. Such a calculation shows that at 2500°K the fraction of the ion current actually emitted which would be removed by recombination is 6.5×10^{-7} . It is therefore seen that recombination does not measurably influence the measurement of the positive ion current.

PROBABLE IONIZATION OF ATOMS AFTER EVAPORATION

One may reasonably ask whether the ions might not be formed from atoms after they evaporated. Ions certainly exist in the vapor of metal in equilibrium with the metal itself, if the temperature is high enough even though the metal emits electrons but no ions. The concentration of positive ions in such a vapor may be obtained from Saha's ionization equation, and some idea of the rate of formation of ions in such a vapor may be obtained by calculating the number of collisions which occur with sufficient energy to ionize, and the number formed by the action of radiation from the hot metal. Such calculations have been made by the writer with the result that the maxi-

num rate of formation of ions from neutral atoms in the vapor is entirely negligible compared to the ion currents measured.

PHOTOELECTRONS FROM THE COLLECTING ELECTRODE

The effect of radiation from the filament in producing photoelectrons from the collecting electrodes which would thereby influence the ion current measured has been investigated in several ways. In the first place Jenkins applied a magnetic field at right angles to the ion current in his Coolidge x-ray tube which was of sufficient strength to prevent electrons leaving the cathode from arriving at the target when a positive potential was applied to it equal to the negative potential used to collect the ions. This had no effect on the ion current which could be true only if heavy ions alone were conducting the current. Similar magnetic experiments performed by the writer produced no effect on the ion current. Collecting electrodes of different metals were used but they produced no changes in the ion current or the variation of it with temperature. The photoelectric effect does not therefore account for a measurable part of the current observed.

POSSIBILITY OF AN APPARENT WORK FUNCTION

It appears then that positive ions of the metal are actually emitted from the metal and the amount of heat required to emit them is less than the amount deduced from cycle (9) the latter of which should be the true heat required. It seems necessary in order to overcome this discrepancy to assume that the value of ϕ_+ obtained from cycle (9) is the true work function for positive ions while the value ϕ_+ determined from the positive ion current is an apparent work function, just as it was necessary to assume in the Sommerfeld¹⁴ theory of the Richardson effect that the true electron work function is W_a , and the value ϕ_{-0} determined by actual measurement is only apparent. In the Sommerfeld theory

$$\phi_{-0} = W_a - W_i$$

Where W_a is the true work required to remove an electron from the metal and W_i is the maximum energy which the electrons already have in the metal due to their high velocities acquired as a result of the velocity distribution law of the Fermi Statistics. It should be pointed out that W_a should not replace ϕ_- in cycle (9) because ϕ_- actually represents the work required to remove an electron which already has the energy W_i . The term W_i occurs implicitly in cycle (9) in the heat of condensation term U , since in condensing the atoms together to form the metal, part of the heat U must have been used up in giving the free electrons the energy W_i .

In the case of positive ions, the degeneracy condition which gave the electrons their high internal energy W_i , is not fulfilled due to their large mass, and their internal energy is the relatively small amount given by classical theory. Hence the question concerning a W_i for ions does not arise. However if it is to be assumed that ϕ_{+0} is an apparent work function then there must

¹⁴ Sommerfeld, *Zeits. f. Physik* 47, 27 (1928).

exist a source of energy of an amount ψ , which is not included in one of the terms in Eq. (9) and the magnitude of which is equal to that required to close the cycle (9). Such an amount of energy could not be supplied through the agency of a force field tending to repel the ion from the metal since such energy would be implicitly included in the work function ϕ_+ .

It may be that tungsten and molybdenum slowly recrystallize in an irreversible manner at high temperatures yielding the necessary energy ψ to emit an ion. The ions would thus be emitted as a secondary effect. In all probability some electrons and atoms would be emitted as a result of the recrystallization but the number thus emitted would be small compared with the number actually emitted per second per cm^2 and would not therefore measurably effect the heat of evaporation of atoms or the electron work function. This may readily be seen by noting that at 2500°K , 3.52×10^{16} atoms of Mo evaporate per sec per cm^2 while only 1.53×10^{11} ions are emitted.

It must be concluded from the foregoing investigation that some, if not all, hot metals emit positive ions of their own metal as well as neutral atoms and electrons. The analysis made above shows that the mechanism of emission of electricity from hot metals is not clearly understood especially as regards the emission of positive ions, for, unlike the evaporation of electrons and neutral atoms, the evaporation of ions is not strictly represented by an equation based upon thermodynamical arguments under equilibrium conditions.

The writer wishes at this time to express his appreciation of the constant help he has received from Professor R. C. Gibbs under whose direction this work was carried out, of the valuable suggestions received from Professor E. H. Kennard and of help given from time to time by other members of the Cornell faculty interested in this work.

ON THE EARLY STAGES OF ELECTRIC SPARKS

BY ERNEST O. LAWRENCE AND FRANK G. DUNNINGTON
UNIVERSITY OF CALIFORNIA

(Received January 3, 1930)

ABSTRACT

With the Kerr-cell electro-optical shutter of Abraham-Lemoine and Beams, phenomena in the early stages of sparks between electrodes of Zn, Cd and Mg have been studied. It was found that, during $50(10^{-8})$ sec after beginning of the sparks, the spark doublet lines $3d_{1,2}-4f_{1,2}$ of Zn have widths of 45A, while the corresponding lines of Cd and Mg are about 30A in width. The luminosity of the metallic vapors of Zn, Cd and Mg was observed to spread from the electrodes with speeds of $2.1(10^5)$ cms/sec, $1.5(10^5)$ cms/sec, and $1.2(10^5)$ cms/sec, respectively. Photographs of the early stages of single sparks with exposure times as short as $4(10^{-8})$ sec were obtained. The snapshots showed that during these short intervals of time after beginning of a spark the discharge is confined to a filament having a cross-section at the anode of $5(10^{-4})$ cm² which broadens out to four times this size at the cathode. From the circuit constants and these dimensions of the discharge it was accordingly estimated that the discharge current density attained the magnitude of $1.7(10^6)$ amps/cm². The asymmetry of the photographed images of the sparks disappeared when the exposure times were extended to include a complete cycle of the discharge, thereby proving the satisfactory operation of the shutter.

Assuming that the broadening of the lines to be due to the Stark effect of inter-ionic fields and with the aid of existing data on the Stark effect behavior of the lines, it was calculated that the average inter-ionic field was 10^6 volts/cm. This result in turn implies that the average separation of the ions was $3.8(10^{-7})$ cm and therefore that 1/3 of the molecules in the path of the discharge were ionized. Approximately the same degree of ionization follows from the assumption that 1/2 of the discharge current is carried by the positive ions moving towards the cathode with the observed velocity of $2.1(10^5)$ cms/sec.

Four more or less independent methods of estimating the temperature of the early periods of the spark from the present observations lead to values of the order of magnitude of $10,000^\circ\text{K}$ which point to thermal ionization as a prominent feature of such discharges.

INTRODUCTION

ELECTRIC sparks have been studied extensively for a long time and yet much remains to be understood concerning the physical process involved. One of the great remaining mysteries¹ centers around the observations of Pedersen,² Rogowski,³ Torok,⁴ Beams,⁵ Peek,⁶ Burawoy⁷ and others that sparks sometimes break down in time intervals of about 10^{-8} sec after ap-

¹ Loeb has proposed a solution of the difficulty, *Science* **69**, 509 (1929).

plication of electric fields. Their work and the work of Lawrence and Beams⁸ made it clear, moreover, that during such short time intervals the voltage across a spark gap drops from its initial high value to low values characteristic of arcs. Thus, the interesting high voltage processes which distinguish a spark from an arc occur during such short intervals of time that they are not easily susceptible to experimental observation.

However, several experimental methods have been developed which have contributed valuable information of the above mentioned sort. Pedersen² used Lichtenberg figures to measure spark lags, Rogowski³ developed a high speed cathode ray oscillograph and studied time variations of potential across spark gaps, Torok,⁴ Peek⁶ and others used surge or transient voltages of very short duration in their studies of sparks, and Anderson and Smith⁹ devised a revolving mirror camera and obtained interesting information on the early phenomena occurring during the "explosion" of wires. The adaptation by Beams¹⁰ of the electro-optical shutter of Abraham and Lemoine¹¹ to the studies of the relative time of appearance of spectrum lines in spark discharges has perhaps pointed to one of the best ways to the attack of the problem of the early stages of sparks, because the Kerr cell optical shutter makes it possible to view sparks during the desired short intervals of time.

The present paper is concerned with such an experimental study in which, for example, snapshots of single sparks with exposure times as short as $4(10^{-8})$ sec. have been obtained, which show interesting features of the early state of affairs in the discharge.

APPARATUS

The apparatus (Fig. 1) consisted essentially of a spark gap *SG*, with condenser *C* in parallel, connected across a source of high voltage *T*, and an electro-optical shutter placed in the optical path between the spark gap and the light recording device at *P*. The latter was either a spectrograph or a camera. When the spectrograph was used, the source of high voltage was

Fig. 1. Experimental arrangement.

simply a 25,000 volt 1 KW transformer which supplied a 60 cycle voltage of any value up to its maximum. When the camera was used a high voltage kenotron (KM-1) rectifying tube was inserted at *X* together with a resistance of about 500,000 ohms. The electrodes of the spark gap made of Zn, Cd or Mg were shaped so that the spark jumped between two parallel faces

6 mm apart. The dimensions of these faces were, when using the spectrograph 3×6 mm (the short dimension being perpendicular to the optical path), and when using the camera, 3×3 mm. The spectrograph was a Hilger constant deviation type having a dispersion of about 36Å per millimeter at 4900Å. The camera consisted of a plate holder and bellows to exclude light, no lenses other than L_1 and L_2 being necessary.

The electro-optical shutter which was the heart of the apparatus was essentially the same as that described by Beams,¹⁰ but with certain minor though important modifications. A Kerr cell consisting of parallel plates 9.5 cm long, 1.2 cm wide and 0.5 cm apart immersed in carbon bisulphide and situated between crossed Nicol prisms N_1 and N_2 was attached to the terminals of the spark gap by wires of variable length. This system operated as an optical shutter controlled by electrical means in the following manner. With no voltage on the Kerr cell, the carbon bisulphide was not doubly refracting and hence light could not pass through the crossed Nicols. Upon application of a potential across the cell the liquid became doubly refracting and a fraction of the light was passed, within a limited range of voltages the amount of light passed being proportional to the fourth power of the voltage. Now since the voltage which was impressed across the gap and condenser was also impressed across the Kerr cell, by the time the voltage had built up to a value sufficient to cause a breakdown of the gap the shutter was open. When the gap broke down the voltage across it dropped to a relatively small value in a time interval at least not greater than 10^{-8} sec. A resulting discharge wave was propagated along the wires to the Kerr cell causing a lowering of the voltage across the plates at a time after the spark breakdown approximately equal to the length of wire in one lead from SG to KC divided by the velocity of light. At about the same time that this discharge wave started from the gap, light from the spark began to be emitted and traveled towards the Kerr cell system. A part of the light which reached the cell before the wave was transmitted, while all of the light reaching the shutter thereafter was rejected. Thus it was possible to observe the light from the spark from its beginning up to any desired time of cut off determined by the lengths of the trolley leads. The times of cut off in the present experiments ranged from practically zero to 50 (10^{-8}) sec. after beginning of the spark.

The modifications in the electro-optical shutter had to do with the control of oscillations. It is obvious that if oscillations should exist in the Kerr cell circuit after the voltage is supposedly reduced to a low value, light from later periods of the spark would be transmitted, thereby producing spurious results. Because previous work has been questioned¹² on this basis, it is believed worthwhile to give some of the details and show proof that the shutter operated in the manner outlined above. The methods used to control the oscillations in the trolley circuit were as follows

(1) *Reduction of coupling between the condenser-spark gap circuit and the trolley-Kerr cell circuit to a minimum.* Upon breakdown of the gap, the dis-

¹² Gaviola, Phys. Rev. 33, 1023 (1929).

charge of the condenser C through the gap is oscillatory. If the coupling between this condenser-spark gap circuit (hereinafter referred to as the condenser circuit) and the spark-gap-trolley-Kerr cell circuit (hereinafter referred to as the trolley circuit) were appreciable, forced oscillations would be produced in the latter. With this in mind the length of path in common between the two circuits was reduced to a minimum by taking off the leads to the trolley circuit by taps in the electrodes about a millimeter back from the sparking surfaces. The coupling was further reduced by taking off these leads to the trolley in a plane at right angles to the condenser circuit.

(2) *Maintaining the fundamental wave-length of the condenser circuit always considerably under that of the trolley circuit.* The trolley circuit consisting of distributed inductance and capacity has a fundamental oscillatory period of its own. It is obvious that even though the coupling were small, the effect in the trolley circuit of oscillations in the condenser circuit would be much greater at or near resonance. To avoid the effect of harmonics as well as that of the fundamental oscillations of the condenser circuit, its wave-length was adjusted so as to be considerably less than that of the trolley circuit. The wave-length of the condenser circuit was calculated and checked by a wavemeter. That of the trolley circuit was obtained by comparison with the condenser circuit by resonance in the following manner. The trolley leads to the gap were disconnected and joined together and the plane of the leads was turned so as to increase the mutual inductance of the circuits. For every set of condenser circuit constants that gave a wave-length within the range of that of the trolley circuit, a position of the trolley could be found that allowed light to pass. Approximate calculations showed that such resonance between the circuits involved fundamentals and not harmonics of the condenser circuit.

(3) *Damping of the oscillations in the trolley circuit.* Even though the trolley circuit were free of all outside disturbances, the charge stored by its distributed capacity previous to a breakdown of the spark would oscillate upon the shorting of the gap by the spark. If these oscillations were critically damped by the insertion of sufficient resistance R_c , the rate of fall of voltage across the Kerr cell would thereby be greatly diminished. However, this impasse to arranging the circuit so that the shutter closes with great rapidity free of appreciable oscillations is only apparent. The intensity of the light passed by the shutter is proportional to the fourth power of the voltage. Hence were the amplitude of the voltage on the first reversal only damped to a value one half the original voltage, the light passed per unit time would be only a sixteenth that at the original voltage. Thus, since the delay in the voltage-drop caused by damping is small until the region of critical resistance is reached, it is possible to damp the oscillations sufficiently without appreciably delaying the closing-time of the shutter. Exact calculations being difficult, the best value for the damping resistance was found experimentally by finding the value which gave the smallest observed distance of migration of the metallic vapor out from the electrodes (see results). The value found was 500 ohms (250 ohms distributed over each lead from spark gap to Kerr cell).

Oscillations were apparent when using resistances considerably below this value. Increasing the damping resistance produced little effect until values of over 1000 ohms were reached when the slowing down of the rate of closing of the shutter became observable

That the shutter was effectively closing at times close to those calculated from the wire path was definitely proved by the direct photographs of the spark (see results). When the time of cut off was made equal to or less than that of a half cycle of the condenser circuit, the pictures obtained were assymmetric relative to the cathode and anode, the images of the discharge being narrower and more intense near the latter electrode. This experimental observation constitutes indisputable evidence that the shutter operated in the manner outlined above.

THE EXPERIMENTS

The initial experiments were concerned with observations of spectra emitted during early stages of the spark. An image of a portion of the spark near one electrode was projected through the optical shutter and was focused lengthwise on the slit of the spectrograph and photographs of the spark spectra of Zn, Cd and Mg were obtained with the shutter closing at various times after the beginning of the sparks. In order to obtain sufficient blackening of the photographic plates it was necessary to expose for from 3 to 10 minutes. Since 120 sparks occurred per sec. the photographs represent the integrated spectra of the beginning of a large number of sparks. The general features of the results were the same for the three metals studied and therefore only the data on Zn are here exhibited. Fig. 2h shows the spectrum of the Zn spark obtained with the Nicol prisms uncrossed, being consequently the ordinarily observed spark spectrum. The Zn spark doublet 4912-24Å and the arc lines 4680Å, 4722Å and 4811Å together with several air lines are prominent. 2a exhibits the spectrum observed with the shutter closing $19 (10^{-8})$ sec after the beginning of the spark—a spectrum which bears little resemblance to 2h. As the experiments of Schuster-Hemsalech¹³, Beams¹⁰ and others have shown, the metallic lines of the spark are absent in its early stages, the spectrum being that of air with a strong continuous background. Taking into account the dependence on wave-length of the photographic sensitivity of the plate and the absorption in the optical system it is estimated that the maximum intensity of the continuous spectrum occurred well below 4600Å. It is of particular significance to note the extreme diffuseness of the air lines during this early period of the spark which is attributed to the Stark effect of the inter-ionic fields

Fig. 2b shows the spectrum photographed with the shutter closing $27 (10^{-8})$ sec after the beginning of the spark. In this photograph, as in all the others, light which produced the lower ends of the spectrum lines came from the region of the spark adjacent to one of the electrodes and the length of the lines represents about 2 mm of the gap. The continuous background at this later time appears definitely to be most intense near the electrodes.

¹³ Schuster and Hemsalech, *Phil. Trans.* 193A, 189 (1900).

This photograph indicates also that the position of maximum intensity of the continuous spectrum shifts to a slightly longer wave-length at this later time. This photograph also shows the first appearance of the Zn metallic spark doublet 4912-24A as a very diffuse region of luminosity near the electrodes. The broadening of the lines is more easily seen in 3g which is

Fig. 2. Photographs of spectra emitted during various intervals of time after beginning of sparks between Zn electrodes in air.

a magnified section of 2c. It was estimated from these observations that each of the *spark lines during this early period of the discharge were broadened symmetrically to a total width of 45A*. The widths of the corresponding lines of Cd and Mg were observed to be somewhat less—approximately 30A.

Fig. 2c shows that at the later time of 50 (10^{-8}) sec after the beginning of the spark, the metallic spark lines were emitted at a greater distance from

the electrodes. This observation gives at once a measure of the average velocity of migration of the metallic ions away from the electrode surfaces. From several such observations it is found that *during the first 27 (10^{-8}) sec the average velocity of migration of the metallic ions away from the electrode surface is $2.1 (10^5)$ cms per sec.* The corresponding observed velocities for Cd and Mg ions were 1.2×10^5 cm/sec and 1.5×10^5 cm/sec respectively. Due to photographic difficulties, these values however are much less accurate than that for Zn.

The above mentioned spectra were taken with a distributed resistance in series with the Kerr cell of 500 ohms. Reducing this resistance to 300 ohms produced no perceptible change—as shown by the spectrum 2d which was taken under the same conditions as 2c excepting that the resistance was reduced to the lower value. On reducing the resistance to 100 ohms, 50 ohms and practically zero, however, a marked effect resulted as shown by Fig. 2e, f and g. From the fact that the luminosity of the spark lines extended further from the electrodes in the latter cases and that even the arc lines were in evidence, it is concluded that the oscillations were of sufficient magnitude to reopen the shutter at a later time. Careful examination showed that the operation of the shutter was sensibly independent of the damping resistance over the range 300 to 1000 ohms. Inserting resistance in excess of 1000 ohms over damped the discharge of the Kerr cell to such an extent that its effective time of closing was perceptibly delayed. Though it was not possible to make an accurate estimate, a calculation from the dimensions of the circuit agreed with the above values as being the right order of magnitude to damp the oscillations to the extent desired.

Our photographs fail to show the metallic arc lines at all, during 50 (10^{-8}) sec after beginning of the spark, a result not in agreement with the observations of Beams¹⁰ and Locher.¹⁴ A faint haze of luminosity near the electrode of wave-length near 4811A shown in 2c might easily have been thought to be due to the Zn arc line 4811A. However, measurements show that it is nearer 4817.5A. The origin of this line is uncertain at the present time as there are no well known Zn or air lines of this wave-length.

The photographs 2a, b, c, show a diffuse air line near 4865A (indicated by arrow) which occurs only in these very early periods of the discharge. 2a shows it extending practically across the spectrogram while in 2b and 2c it is confined successively nearer the lower edge. As will be evident in the discussion, very intense ionization and accompanying high temperature exists in the early period of the spark and it is probable that this line therefore is due to an ionized constituent of the air. There are many examples in the literature of lines which appear only under such conditions.¹⁵

For the purpose of measuring the cross-section of the discharge during its early development in order to obtain an estimate of the current density, direct snapshots of the spark of the requisite short exposures were attempted. A kenotron and a one-half megohm resistance inserted in series with the

¹⁴ Locher, J.O.S.A. and R.S.I. 17, 91 (1928).

¹⁵ Handbuch der Physik 21, p. 434.

condenser made it possible to apply known differences of potential across the spark gap resulting in single sparks. Images of the spark projected through the Kerr cell and focused on a photographic plate are shown in Fig. 3. The polarity indicated in all the photographs is that of the first half cycle. 3a is a series of single sparks taken with the Nicol prisms uncrossed (with the

Fig. 3. Photographs of the early stages of sparks between Zn electrodes.

shutter continuously open) and therefore represent images of completed sparks. 3d shows the spark during the first 4 (10^{-8}) sec of its existence. To obtain these photographs it was necessary to have a condenser capacity of 0.004 mf in order to maintain the oscillations in the spark circuit out of resonance with the Kerr cell circuit. It is seen that *the discharge is confined*

to a very narrow filament near the anode which widens out towards the cathode. Measurement of the plates showed that the average diameter of the discharge at the anode was 0.25 mm and at the cathode 0.5 mm. Since the period of oscillation of the spark was $26 (10^{-8})$ sec, these photographs represent the form of the discharge during the earlier part of the first half cycle. Changing the condenser capacity to 0.008 mf, the photographs of 3c were obtained with the shutter closing $7 (10^{-8})$ sec after the breakdown of the potential across the gap. In this instance the period of oscillation was $36 (10^{-8})$ cm and consequently these are pictures of approximately the first quarter cycle of the discharge. The dissymmetry of the discharge is still evident, though not as marked as in the shorter exposures,—the average diameter of the discharge at the anode being 0.45 mm and at the cathode 0.5 mm. Another interesting feature of these photographs is the presence of a *very bright spot of luminosity close to the anode*, indicating an intensity of light there greatly in excess of that of the central section of the filament. 3b was obtained with the shutter closing at $27 (10^{-8})$ sec. In this instance the shutter closed after the setting in of the second half cycle, as the period of oscillation remained at $36 (10^{-8})$ sec. As was to be expected, this photograph shows a more nearly symmetrical filament with minute intense spots of light at both electrodes, that at the cathode being less intense than the one at the anode because the cut off occurred at about the middle of the second half cycle. The average diameter of the filaments is 0.5 mm. It is perhaps not amiss to emphasize again that *these observations of the asymmetry of the discharge during the first half cycle are indisputable evidences that the electro-optical shutter functioned in the manner outlined above and that oscillations were of inappreciable magnitudes.*

Thus during the period of $23 (10^{-8})$ sec between the closing of the shutter for groups d and b, the cross-section of the discharge at the anode was observed to vary from $4.9 (10^{-4})$ sq cms to $1.9 (10^{-3})$ cm² and since during these periods the average discharge currents (estimated from the circuit constants) were 800 and 1100 amps respectively, *the average current density varied from $1.7 (10^6)$ amps per cm² to $5.8 (10^6)$ amps per cm².* These enormous current densities produced the great brilliance of the spark which made possible the short exposure photographs of the present experiments.

The path of breakdown of the sparks usually were along the lines of force. When the electrode surfaces were flat with sharp edges the sparks jumped from edge to edge along the curved lines shown in many of the photographs. When the edges were rounded off the sparks jumped between the middle of the electrode surfaces along the straighter lines of force in that region. However, interesting exceptions have been observed during the first $3Q (10^{-8})$ sec of the spark as shown in Fig. 3, e and f. 3f shows a sharp spur protruding from the main filament of the discharge of the sort that might arise from an ion path initiated by a high velocity particle. The spur is bent away from the anode and luminosity is seen to extend outside the main discharge from the spur to the cathode, as though positive ions formed along the path of the spur produced additional luminosity during their

passage to the cathode. 3e shows a case where the spark took two simultaneous paths, the bifurcation suggesting that the spark breakdown was initiated at the cathode. Examples of bifurcation at the anode and also in the middle of the gap, however, have been observed.

DISCUSSION

There can be little doubt that large broadening of spectrum lines produced by high current densities is due to the Stark effect of inter-ionic fields.¹⁶ The width of the spark doublets of Mg, Cd and Zn observed in the early stages of the spark therefore can serve as a measure of the average ionic fields, and in turn, the average number of ions per cc in the discharge. Such an estimate requires an independent knowledge of the Stark effect behavior of the lines. Now the spark lines in question result from transitions between the hydrogen like energy levels $3d_{1,2}$ and $4f_{1,2}$ and indeed are very similar to the corresponding line 4686Å of ionized helium. It is therefore to be expected that the metallic spark lines should exhibit a Stark effect closely resembling the observed Stark effect of the corresponding He line. Several experimental measures of the Stark effect of the He line in question have been made, the most recent being that of Foster¹⁷ who finds that the maximum displacement of the components from the undisplaced position is about 2.4Å per 100,000 volts/cm field. The results of Nagaoka and Sugiura¹⁸ show that the corresponding line 4811Å of Mg is broadened to a width of about 2Å on each side of the undisplaced position in an average field of 116,000 volts/cm, a fact which supports the expectation that the corresponding lines of He, Zn, Cd and Mg should exhibit nearly the same Stark effect. From the total width of 45Å observed in the present experiments then it can be concluded with considerable confidence that *the average ionic field during the early stage of the Zn sparks here studied was approximately 10^6 volts per cm.*

From this value for the average ionic field and the inverse square law it follows that the average separation of the ions was approximately 3.8 (10^{-7}) cm and therefore that the total number of ions and electrons was about $1.8 (10^{19})$ per cc. *Thus, about 33 percent of the molecules in the path of the discharge were ionized.* Anderson and Smith⁹ have found an equally great degree of ionization during the early stages of the "explosion" of wires.

The present experimental data lead to a second and independent estimate of the ionic density. The average velocity of migration of the metallic spark luminosity, and therefore presumably of the positive ions away from the anode was observed. Assuming that the positive ions moved towards the cathode with this speed and carried one-half the discharge current, it follows that there were necessarily present about $0.82 (10^{19})$ positive ions per cc. Thus, this second estimate indicating 30 percent ionization is in excellent agreement with the first.

¹⁶ An excellent resume of the subject of the broadening of spectrum lines is to be found in volume 21 of the "Handbuch der Physik."

¹⁷ Foster, Astrophys. Jour. **62**, 229 (1925).

¹⁸ Nagaoka and Sugiura, Jap. Jour. of Phys. **3**, 46 (1924).

The objection might be raised perhaps that, because of the far greater mobility of the electrons, they carry most of the current of the discharge and consequently it is not valid to assume that half the current is carried by the positive ions. Loeb¹ states, for example, that the electrons have about 1000 times the mobility of the positive ions. However, such estimates are made with the assumption that the density of the ions is small compared to the density of the neutral molecules, a state of affairs existing in low current-density discharges. The above results make it clear that in the early stages of sparks because of the high degree of ionization a pumping action of the ions produces a general flow of both ions and neutral molecules resulting thereby in a greater mobility of the ions than calculated in the usual manner. Moreover, a simple calculation shows that the high current density of the discharge produced a magnetic field as great as 20,000 Gauss which exerted a great influence on the trajectories of the electrons. Thus, if the velocity of the electrons were 10^8 cms/sec perpendicular to the magnetic field, it is calculated that the magnetic field caused them to travel in curved paths with radii of curvature $3 (10^{-4})$ cm. The effect of the magnetic field was consequently to increase greatly the paths traversed by the electrons in passing from cathode to anode, thereby producing a great reduction of their general drift velocity (mobility). Space charge effects played an unknown though probably important part also in keeping the electron current and the positive ion current at the same order of magnitude.

Several independent estimates of the temperature may be made as follows.

(1). From the degree of ionization the effective temperature of the discharge can be calculated after the manner of Saha.¹⁹ We have the reaction-isochores

$$\log \frac{x^2}{1-x^2} P = -\frac{5050 V_i}{T} + 2.5 \log T - 6.69.$$

where x is the fractional number of the atoms ionized, P is the pressure in atmospheres, V_i is the ionization potential in volts and T is the absolute temperature. Taking for x the here-observed value $1/3$, for V_i 9.3 volts, the ionization potential of Zn, and for P , 10 atmospheres, there results for the temperature of the discharge the value of $13,500^\circ\text{K}$. A higher assumed value for V_i corresponding to ionization of O or N would lead to a correspondingly higher estimate of the temperature. However, the observations were taken in the proximity of the electrode where the metallic vapor predominated. From the observed spreading of the filament of the discharge during the course of time, from the work of Anderson and Smith on exploded wires, and from other considerations, it appears that the assumed pressure is right in order of magnitude.

(2). It is also possible to make a rough estimate of the temperature of the discharge from knowledge of the rate of dissipation of energy in the spark. Professor J. W. Beams has kindly let us see some of his revolving mirror

¹⁹ Saha, Proc. Roy. Soc. A99, 135 (1921).

photographs of sparks in advance of publication from which we deduce that the sparks we worked with had a duration of the order of magnitude of 10^{-5} sec, and therefore that about one one-hundredth of the energy of the discharge was dissipated in the spark during the first 10^{-7} sec. Knowing in addition the capacity of the condenser, the voltage at breakdown, the specific heat of the, and the volume of the gas heated, an elementary calculation leads to 5000°K as the temperature of the discharge. This estimate is somewhat lower than that resulting from Saha's equation, a fact that is to be accounted for by the assumption that only $1/100$ of the energy stored in the condenser is dissipated in 10^{-7} sec. Beams has shown in his revolving mirror photographs that the first cycle of the spark discharge has a period about 1.5 times longer than the period of later oscillations and therefore that the resistance and rate of energy dissipation is greater at the beginning of the spark. This fact was also taken into account in estimating the current density in the above calculations.

(3). As has been pointed out above, the high degree of ionization produced a general flow of ions and neutral molecules to such an extent that the observed velocity of migrations of the ions probably also measured the average velocity of the molecules. An estimate of the temperature then follows from

$$(3/2)kT = (1/2)mv^2$$

where k is Boltzman's constant, T is the temperature, m is the mass of a Zn atom and v is the observed velocity. Such an estimate yields a temperature of $10,900^{\circ}\text{K}$.

(4). Finally, an estimate of the temperature may be made from the intensity distribution in the continuous spectrum of the discharge. From the observation that the intensity was a maximum well below 4600\AA , it is concluded that the discharge temperature was considerably above 6200°K . This value is least reliable of all because many sources of error in estimating light intensities were not carefully investigated.

Thus, four more or less independent estimates of the temperature of the sparks obtained from the data of the present experimental study agree in indicating that it is of the order of magnitude of $10,000^{\circ}\text{K}$. This result points to thermal ionization as the main process in the early stages of sparks as has been suggested by Slepian.²⁰

A NEW REGULARITY IN THE LIST OF EXISTING NUCLEI

BY HENRY A. BARTON

DEPARTMENT OF PHYSICS, CORNELL UNIVERSITY

(Received January 13, 1930)

ABSTRACT

In the absence of a theory of nuclear constitution, a search for regularities in the list of existing nuclear types is of value. Aston's data form a fairly complete list up to atomic number 61. Previous investigations disclosed evidence of several types of regularity. A new type has been observed in which most of the known nuclei in the range studied fall into three clusters, each characterized by a two dimensional symmetry. More specifically, when the nuclei are plotted as points whose ordinates and abscissas indicate the number of protons and electrons respectively in their constitution, there exists for each cluster a center (P, E) such that if there is a nuclear type $(P-X, E-Y)$ there is, in general, also a symmetrical type $(P+X, E+Y)$. A consideration of the relatively few departures from this rule within the clusters leads to a list of *predicted isotopes* as yet undiscovered. A possible physical interpretation of the new type of regularity is tentatively suggested. The considerations advanced apparently do not apply to a number of points scattered through the regions between the clusters.

INTRODUCTION

THERE is no comprehensive theory of the structure of atomic nuclei. The present position is one in which it is very desirable to examine the available data in search of empirical laws with which to simplify the statement of what is known. The list of nuclei embracing all known isotopes of all elements which actually exist, in contra-distinction to those conceivable nuclei which do not, presents a fruitful field for such a scrutiny. Any rule or regularity of occurrence which can be found will facilitate the development of a satisfactory theory. Beck¹ has pointed out that Aston's work has now furnished a body of excellent data² covering nearly all elements up to atomic number 61. A knowledge of the isotopes of many elements heavier than this is as yet lacking so that the data do not have the completeness which is necessary, or at least most desirable, when it is a question of the existence or non-existence of each possible nucleus. Only that part of the list of elements which lies below atomic number 61 is considered in the present paper. For such a list presented in significant tabular form the reader is referred to Beck's papers.

The considerations which Beck advances lead to valuable rules in addition to those already noted by others.³ The work of Harkins,⁴ based on evidence

concerning the relative abundance⁵ of the elements in the earth's crust and in meteorites, has been particularly fruitful in establishing rules governing the existence and stability of nuclear types. The kinds of regularity pointed out by these and other authors deal with the numbers of α -particles, protons, and electrons in the nuclei. For example, the fact that mass increments of four units together with charge increments of two units occur frequently in almost any sort of classification gives strong evidence of the existence of

Fig. 1. Constitution of all known nuclear types in the range of elements below atomic number 61.

nuclei which differ from one another merely in the number of integral α -particles they contain. Other rules are, for example, the tendency for the number of nuclear electrons to be even, the limitation to two isotopes in the cases of elements of odd number, etc.

A NEW TYPE OF REGULARITY

The writer has recently observed an altogether different type of regularity which does not seem to be described in the literature. It appears when a

⁵ F. W. Clark, "The Data of Geochemistry," Bulletins 491 (1911) and 616 (1915), U. S. Dept. of the Interior. "Evolution and Disintegration of Matter," U. S. Geol. Surv., Prof. Paper 132-D (1924). W. D. Harkins, J. Am. Chem. Soc. 39, 856 (1917).

suitable chart is made of the constitution of the existing nuclei. Fig. 1 is such a chart in which a point is plotted for each nucleus opposite the ordinate P representing the number of protons it contains and the abscissa E representing the number of electrons it contains. P , the number of protons, is approximately equal to the atomic mass. E stands for *all* of the nuclear electrons whether constituting α -particles or not, so the atomic number, or nuclear charge, Z , is equal to $P - E$. The chart was compiled from Aston's data.

It is evident even on this small scale chart that there are three clusters of points separated by regions of relatively low density, i.e., where the ratio of the number of actual to conceivable nuclei is relatively small. The clusters themselves are individually of interest. A superficial examination of a small

Fig. 2. Enlargement of the middle portion of the chart in Fig. 1 to show the two-dimensional symmetry of the cluster. (Cluster II.)

chart such as Fig. 1 gives little basis for specifying the limits or centers of the clusters. On a larger scale, however, it is apparent that in each group there exists a regularity in the form of a two dimensional symmetry about a definite point near the center of gravity of the clusters. For example, Fig. 2 shows the region of Fig. 1 occupied by the middle cluster. The solid dots are the same as those of Fig. 1. The circles show the positions occupied by the dots in the upper right quadrant if that quadrant is rotated 180° around the axis of symmetry $P = 80$. The extent of the symmetry can now be estimated at a glance. In this cluster, evidently centered at $(P, E) = (80, 45)$, the symmetry is perfect except that in the cases of four out of the thirty-two points plotted, the symmetrically located positions are vacant. Such vacant positions are indicated by question marks.

Similar charts of the clusters in the regions of heavier and lighter elements respectively are shown in Figs. 3 and 4. In the cluster made up of heavier elements, it is noteworthy that the symmetry, centering at (124,72) consists largely of two long diagonal lines of points. One of these, starting at (124, 74), runs one way to (112,62), and the other starting at (124, 70), runs the other way to (136,82). The one represents the isotopes of tin and the other the isotopes of xenon. Although two positions are vacant in the case of xenon, the end positions of the two lines are symmetrical, and in each case, the outer end is followed by several points in a vertical row.

Fig. 3. Cluster III; heavier elements.

Fig. 4. Cluster I; lighter elements.

The cluster in the region of lighter elements presents so simple a type of symmetry that the center cannot be located without ambiguity. The point (25,13) would serve as well as (27,14). The discovery of the new oxygen isotopes⁶ (shown by circles) would tend to shift one's estimate of the "center of gravity" of the cluster downward.⁷

Aston has recently published the result of some further experiments with the mass spectrograph.^{8,9} These must be considered now in so far as they

⁶ W. F. Giaque and H. L. Johnson, *Nature* **123**, 318 and 831 (1929). *J. Am. Chem. Soc.* **51**, 1436 (1929).

⁷ It is interesting to note that the new oxygen isotopes are nuclei which would have been predicted by extrapolation of the obvious step-like regularity of the cluster.

⁸ F. W. Aston, *Nature* **120**, 224 (1927); **122**, 167 and 345 (1928).

⁹ The writer was not aware of these when he published a preliminary notice. (*Phys. Rev.* **34**, 1228 (1929)). He wishes to take this opportunity of also acknowledging his error in including in that notice a nuclear type ($80+11$, $45+7$) which has not been shown to exist. Beck has postulated its existence on fairly firm grounds. However, the writer wishes to confine himself to Aston's experimental data with the addition of the isotopes 17 and 18 of oxygen, 15

affect the symmetry of the clusters. New isotopes of lead, mercury, germanium and zinc are announced. It is not of interest for the present purpose to add the corresponding points to Fig. 1. In fact, lead and mercury are above the range of elements investigated. The isotopes of germanium and zinc alter only Cluster II. To bring Fig. 2 up to date it would be necessary to add points corresponding to the additional isotopes of germanium and zinc, namely (73, 75, 76, 71 and 77) and (67 and 65) respectively. The previously known isotopes were of course already plotted in Fig. 2. None of the new points falls into a position symmetrical with one already existing. The symmetry of this cluster is thereby considerably impaired although strong evidence of the tendency remains.

Aston states⁸ that it is impossible to exclude the possibility that the mass spectrum lines representing some of these isotopes really represent hydrides of the previously known isotopes. Germanium is known to be like carbon in its tendency to form unstable hydrogen compounds, so it would be expected that such hydrides would appear in the discharge tube in the same way as CH , CH_2 , etc. appeared when compounds of carbon were present. The symmetry considerations would be helped if this were found to be the case. On the other hand, it may be that here is an example of the danger of working with only partially gathered data. The relative abundance of the new isotopes is obviously very small since they escaped discovery in Aston's previous study of germanium. It is possible that symmetrical nuclear types of the same order of abundance (very faint isotopes of strontium) may yet be found to restore a high degree of symmetry to the cluster. It is because of these reservations that the cluster has been plotted without, rather than with, the new data.

DISCUSSION

The boundaries of the three clusters as represented in Figs. 2, 3, and 4 are of course, arbitrarily chosen. However, it can be said that there is good evidence of symmetry just inside these boundaries and little of such evidence just outside. There remain, then, the regions below and between the clusters in which fall the points of a number of very common nuclei, among them hydrogen, helium, carbon, calcium, and iron. In these regions no evidence of symmetry has been discovered, so that no claim for applicability over the whole list of natural elements can be made for the type of regularity described in this paper.

Alternative points of view may be taken with regard to the departures from perfect symmetry within the clusters. The vacant positions may be vacant only through lack of data. On the other hand, the existing points symmetrical to these vacant positions may represent nuclei not properly belonging to the cluster in some sense which we do not now know how to define. The first alternative may at least be adopted tentatively. On this

of nitrogen, and 13 of carbon discovered through the band spectra of compounds of these elements. See Ref. 6; also A. S. King and R. T. Birge, *Nature* **124**, 127 (1929); *Phys. Rev.* **34**, 376, 379 (1929); S. M. Naudé, *Phys. Rev.* **34**, 1498 (1929).

basis it is predicted that the question marks in Figs. 2 and 3 represent isotopes which should still be found, perhaps in very small quantity. A list of the isotopes so predicted is given in Table 1.

Note 1. Gives this odd element two isotopes at usual mass interval of two units.

Note 2. Isotopic constitution entirely unknown. Atomic weight of 93.1 would suggest strongly the two isotopes 93 and 95 following the rule for odd elements referred to in Note 1.

Note 3. Atomic weight of 137.37 indicates existence of some isotopes lower than the known 138.

At the foot of the table are some notes as to independent reasons for expecting these isotopes to exist or not to exist in the several cases.

The additional isotopes of germanium and zinc, to which reference has already been made, would demand, on the basis of symmetry, the isotopes 83, 84, 85, 87 and 89 of strontium and 93 and 95 of zirconium.

Even if complete data do not make the symmetry perfect, it is nevertheless a strongly marked tendency and calls for explanation. There is probably not sufficient basis as yet for the serious advancement of a theory. As a point for discussion, however, the suggestion which follows is not out of order.

Consider, for example, the middle cluster whose center is at the point (P_2, E_2) representing a conceivable nucleus consisting of 80 protons and 45 electrons. That this nucleus apparently does not exist is a matter of no concern. Suppose that at an early stage in the evolution of the matter from which terrestrial matter was drawn, there were formed fairly abundantly nuclei of constitution $(2P_2, 2E_2)$, i.e., (160, 90) containing just twice as many protons and electrons as the center of the symmetrical cluster. Such a nucleus has not been found to exist in the earth's crust and may hypothetically be regarded as unstable. Suppose there to be a tendency on the part of this nuclear type to break into just two nearly (but not precisely) equal parts. The products of any one such event would be $(80+X, 45+Y)$ and, since the second part is postulated to contain the rest of the nuclear matter, $(80-X, 45-Y)$. Obviously there would thus come into existence always two nuclei symmetrically located X, Y and $-X, -Y$ units respectively from the sym-

metry center (80, 45). The possible values X , Y would presumably be governed by nuclear forces of cohesion. That is, like a crystal, the nucleus might have particular surfaces of division more probable than others.

To explain the three observed clusters, three transitory parent nuclear types must be postulated. They would have the constitutions: a) (248, 144) representing an element a little beyond uranium and, therefore, almost certainly unstable; b) (160, 90) falling near the upper region of the rare earths; and c) possibly (54, 28) the lesser isotope of iron, or (50, 26) an unknown isotope of chromium.

Nothing has thus far been said about the relative abundance of the nuclear types. On the basis of the suggestion that symmetrical nuclei are natal twins, the observed symmetry of existence would be expected to extend itself to a like symmetry of abundance. Roughly speaking this is not found to be the case. A test of such a consideration is difficult when the elements involved are different chemically. It is possible, however, to observe whether the course of abundance of the isotopes of tin corresponds symmetrically to that of the isotopes of the symmetrically located element xenon. Aston places the tin isotopes in the order 120, 118, 116, 124, 119, 117, 122, 121, 112, 114, 115. A comparison of the symmetrical order for xenon with the observed order of that element is given below:

Expected from symm.	128, 130, 132, 124, 129, 131, 126, 127, 136, 134, 133
Found by Aston	129, 132, 131, 134, 136, 128, 130, 126, 124

It may well be the case that an initial symmetry of abundance has ceased to exist on account of differences in the stability of the several nuclear types, and only the symmetry of existence remains as a relic of the originating process.

Before concluding, it should be acknowledged that the suggestion outlined may be entirely supplanted by an assumption of inherent symmetry in the rules governing the stability of the nuclei. Probably no more explicit statement in this vein may be made for the present.

BLACK BODIES IN THE EXTREME INFRA-RED

BY C. HAWLEY CARTWRIGHT
CALIFORNIA INSTITUTE, PASADENA

(Received December 30, 1929)

ABSTRACT

Absorbing power of various materials of wave-lengths greater than 50μ .—For blackening a receiver of a thermocouple for radiation for obtaining pure rotation band spectra, it is desirable to use a material that is an efficient absorber of the extreme infra-red but a poor absorber of radiation of shorter wave-lengths. The absorbing power of 25 materials were tested for radiation of wave-lengths near 4μ and greater than 50μ . Of all the materials tested, white lead, litharge, red phosphorus, powdered glass, copper sulphide, and celestite were found the best for covering a receiver to absorb the extreme infra-red radiation. The 25 materials were tested by painting them on a receiver of a thermocouple which was exposed to extreme infra-red radiation. The same receiver and thermocouple were used throughout the experiment. A D'Arsonval type galvanometer was improved by using a quartz suspension and replacing each conducting lead with silver leaf or gold plated silver ribbon 1μ thick wound in a spiral.

Glass as a source of extreme infra-red radiation.—Hot glass made a good source of extreme infra-red radiation when used with a cold thin glass shutter.

INTRODUCTION

While working with thermocouples and radiometers in the extreme infra-red, it was found that nothing was known quantitatively of the absorbing qualities of the materials used for blackening the receiver. Since the efficiency of the receiver depends on its absorbing power, it was fundamentally important to know the relative merits of the various materials suitable for blackening a receiver. Twenty-five such materials were selected and comparisons made of their respective absorbing powers for both extreme and near infra-red radiation. It was desired to find a material that was black for infra-red radiation of wave-length greater than 50μ and a poor absorber of shorter radiation and especially adapted for coating a thermocouple or radiometer. Some materials that had no practical usefulness were also tested to see if any were exceptional absorbers of the extreme infra-red.

The experimental difficulties encountered in working with radiation of longer wave-length than 50μ is due mostly to the very small amount of energy available in that region and the interference of the large amount of shorter radiation. Various means are used to filter out the shorter radiation. A black body at 1000°K radiates 57 percent of its energy between 2μ and $5\mu^1$ and only 0.08 percent of its energy in wave-lengths greater than 50μ . Increasing the temperature to 2000°K increases the energy between 2μ and 5μ 12-fold while radiation of 70μ is only increased $2\frac{1}{2}$ times; the proportion is less favorable at 3000°K .

¹ L. L. Holladay, J.O.S.A. 17, 333 (1928).

The small amount of energy available makes it desirable to use a material that is an efficient absorber of long waves; also, it would be desirable if the material were a poor absorber of the near infra-red. The desirability of a material depends on the type of receiving apparatus. For thermocouples, the material should be a good heat conductor, so that it will quickly heat the metal receiver. For radiometers, it is better to use a poor heat conductor so that the back side of the vane will be cool; also, it is better to have a high temperature gradient.^{2,3}

A material that absorbs the extreme infra-red well could be used as a source, if the temperature is not too high to alter the physical or chemical state of the material, so that Kirchoff's law would no longer apply. Here, too, it would be an advantage to use a material that is a poor absorber of the short infra-red.

THE EXPERIMENTAL ARRANGEMENT

The apparatus was essentially that used by most investigators of pure rotation band spectra with regard to the method of isolating the long wavelengths. Fig. 1 shows schematically the apparatus. The source of radiation

Fig. 1. Apparatus.

consisted of an electric heater painted with ground glass in tartaric acid and sugar. The temperature was held constant at 1000°K . The radiation was reflected from a stainless steel mirror that had been ground rough with emery. The average depth of the pits was about 8μ and since the reflection was at 45° , the effective depth was about 6μ . A crystalline window 0.83 mm thick was sooted with camphor smoke, so that it was opaque to sunlight. The thermocouple was a balanced type and was shielded from stray radiation and conduction. The wires were 0.033 mm in diameter and had a high ther-

² G. Hettner, *Zeits. f. Physik* **47**, 499 (1928).

³ Paul S. Epstein, *Zeits. f. Physik* **54**, 537 (1929).

moelectric power. The receivers were gold plated copper 2 mm by 2 mm and 0.008 mm thick. The receivers were waxed to the thermojunctions. Two shutters, one of metal and one of microscope cover glass 0.014 mm thick were used separately and in combination. The galvanometer had a sensitivity of 11 mm microvolt when critically damped. It was found desirable to rebuild the galvanometer in order to get more reliable measurements. The silver ribbon suspension was replaced by a quartz fiber and the conducting leads were each made from a narrow strip of silver leaf. The galvanometer with this arrangement was much improved for there was practically no zero shift even for deflections of two feet at a meter scale distance. Another advantage of this arrangement was that the silver leaf damped out forced vibrations due to earth tremors. A more rugged and simple construction, suggested by Mr.

Fig. 2. Transmission of quartz and thin glass, 0-6.2 μ .

Julius Pearson, consisted of making each conducting lead of a gold plated silver ribbon rolled to 1 μ thickness and wound into a flat spiral.

Fig. 2^{4,5} shows the transmission curve for quartz and a microscope cover glass. The quartz becomes opaque at 5 μ but transmits wave-lengths greater than 50 μ except for a narrow absorption band at 78 μ . The microscope cover glass remains opaque to long wave-lengths.

Four groups of readings were taken, using (1) the metal shutter to exclude all radiation, (2) the glass shutter to exclude all of the extreme infra-red but only a small fraction of the near infra-red, (3) the glass shutter always in and moving the metal shutter to find the effect of the near infra-red, and (4) the metal shutter again to see if conditions had remained constant during the

⁴ Edison Pettit, *Astrophys. J.* **61**, 163 (1926).

⁵ W. W. Coblentz, *B. S. Bull.* **2-3**, 462 (1906).

experiment. Designating by V the energy below 5μ that is received by the thermocouple without any shutter, I the energy above 50μ under the same conditions, and k the fraction of energy below 5μ either reflected or absorbed by the glass shutter, the four groups become:

$$(1), V+I; \quad (2), kV+I; \quad (3), (I-k)V; \quad (4), V+I.$$

(2) and (4) are redundant but are useful as a check and for taking averages. Thus: $(2)-(1)=(3)$ and $(2)+(3)=(1)=(4)$.

The value of k can be seen from Fig. 2 to be between 0.15 and 0.20. The value of k was determined experimentally by using an additional window of microscope cover glass 0.008 mm thick, and using the metal shutter to find V and the glass shutter to find kV . The value of k was found to be 0.18. This value depends on the particular apparatus and in a small way on the material used to blacken the receiver.

The table shows the relative blackness or absorbing power of the different materials tested.

3. Powdered Glass	11.7	5.0	.43	16. Platinum Black	18.2	4.4	.24
4. White Lead 2 Pb				17. Tartaric Acid and Sugar	16.0	3.9	.24
CO ₃ · Pb(OH) ₂	14.9	4.9	.33	18. Talc H ₂ MgSi ₄ O ₁₂	12.5	3.8	.30
5. White Lead in lacquer	14.3	4.4	.31	19. Water glass	12.1	3.7	.31
6. Red Phosphorus	18.3	5.0	.27	20. Tellurium, powdered	19.2	3.3	.17
7. Red Phosphorus from a match box	17.7	5.1	.29	21. India Ink	18.8	3.8	.20
8. Celestite, powdered SrSO ₄	14.7	4.6	.31	22. Lacquer	8.6	3.0	.35
9. Brucite, powdered Mg(OH) ₂	11.4	4.2	.37	23. Castor Oil	8.8	2.8	.32
10. Angelsite, powdered PbSO ₄	14.2	4.2	.30	24. Glycerine	11.2	3.1	.28
11. Copper Sulphide	17.1	5.2	.30	25. Turpentine	8.1	0.2	.02
12. Copper Oxide	13.8	4.4	.32	26. Clean Receiver	2.9	0.2	.07
13. Silver Sulphide	12.8	4.4	.34				

Some of the materials were selected because they were transparent to near infra-red, some because they had been used by investigators of the extreme infra-red. The powdered materials were painted on the receiver by mixing them with one part turpentine and five parts alcohol. After a material was tested, the receiver was carefully cleaned and painted with another material. Care was taken to replace the thermocouple in the apparatus in the same place each time. The absorbing materials were painted with uniform thickness on the receiver and in each case the thickness of the coat was about 0.01 mm as estimated under a microscope.

Water glass was very unsuitable for a delicate thermocouple for it caused the heavy receiver used here to curl. The glue mixed with the red phosphorus taken from a match box also caused the receiver to curl.

Item 25 in the table shows that turpentine did not absorb the long waves. To determine whether they were reflected or transmitted by the turpentine, a receiver painted with white lead in lacquer was covered with turpentine. The far infra-red was absorbed equally well which showed that turpentine is transparent to long wave-lengths.

The absorbing power of a receiver depends on the thickness of the absorbing material. A copper receiver tarnished with H_2S , so that it appeared quite black was about 50 percent efficient in the near infra-red and only 25 percent efficient in the extreme infra-red, compared with a 0.01 mm coat of copper sulphide painted on the receiver. The physical state of the receiver affects its absorbing power. A receiver, electroplated rapidly with copper, so that the surface was rough, absorbed the far infra-red well; it had a ratio of $I/V=0.28$. A heavy coat of platinum black electroplated on a receiver had the same absorption as if it were painted on the receiver.

The transmission of crystalline quartz, hard rubber, and a cellulose paper used for wrapping candy was also tested to compare their merits as window material. The cellulose paper is very strong and gas tight. The same apparatus was used and the radiation made to shine through the sample being tested. The following table shows the percentage of radiation transmitted by the three samples, used as extra windows:

Material	V	I	I/V
Cellulose paper, 0.033 mm	47%	37%	0.79
Crystalline quartz, 0.83 mm	70	23	0.33
Hard Rubber, 1.2 mm	11	6	0.55
Without an extra window	100	100	0.30

The reflection of the far infra-red from a glass surface was tested by replacing the rough mirror by a piece of plate glass. The ratio of the number of waves reflected from the plate glass to the number reflected from the rough steel mirror was 31 percent.

CONCLUSION

It is to be noticed that the absorptive power of the materials tested was an integrated effect extending over the entire far infra-red.

Litharge, powdered glass, white lead, copper sulphide, celestite, and red phosphorus were the best absorbers of radiation longer than 50μ .

The physical state of the receiver determined its efficiency. A very thin coat of the absorbing material in most cases was an inefficient absorber of the extreme infra-red waves. A very poor absorbing material such as copper or platinum will absorb if the surface is sufficiently rough.

For radiometers, the absorbing material is better when mixed with turpentine and alcohol and painted on the vanes. Very delicate fly-wing radiometers were made in this manner, weighing only 0.04 mg. The vanes were double and a sputtered mica mirror was used.

For thermocouples, absorbing material is better if it is mixed with lacquer. The thermocouples must be in vacuum to be steady; in some cases an increase of 60 times the sensitivity was obtained by evacuation.

The high absorption in glass of the extreme infra-red and its low absorption of the near infra-red suggested its use as a source. Such a source was made by covering with glass two platinum wires that were separated 4 mm. The wires were heated by an electric current and the hot portion of glass between the two wires served as a source of extreme infra-red radiation. This source was tested in a vacuum spectrometer⁶ and found to be satisfactory.

A convenient method of filtering out the near infra-red is to grind the windows with emery so that the pits are about 4μ deep. The apparatus can be aligned with visible light by covering the rough surface with turpentine.

Although a tarnished metal surface is not an efficient absorber of the extreme infra-red, it may be desirable to sacrifice efficiency for the extra speed with which the thermocouple will come to thermal equilibrium,—particularly if the readings are recorded photographically. The receiver of a thermocouple can be improved by pressing it against the surface of a file to make the surface rough. A thermocouple with tarnished silver receivers reached equilibrium in one second. White lead is especially desirable for blackening a receiver for it is white to visible light and allows almost perfect alignment of the apparatus.

PELTIER AND THOMSON EFFECTS FOR
BISMUTH CRYSTALSBY H. D. FAGAN AND T. R. D. COLLINS
PHYSICS LABORATORY, UNIVERSITY OF IOWA

(Received November 20, 1929)

ABSTRACT

The Peltier and Thomson effects are directly measured (the former against copper) in single crystal rods almost covering the entire orientation range. For the first effect the Voigt-Thomson symmetry relation is definitely not substantiated, while for the latter the data do not provide an adequate test, though it appears likely that there is a deviation here also.

The following values are found: at a temperature of 27°C , $\pi(\parallel\text{vs.}\perp)=13.8$, $\pi(45^{\circ}\text{vs.}\perp)=8.6$ microvolts; at a temperature of 48.5°C , $\sigma_{\parallel}-\sigma_{\perp}=43$, $\sigma_{45}-\sigma_{\perp}=26.5$ microvolts/ $^{\circ}\text{C}$. These values are all in fair agreement with values deduced from thermal e.m.f. temperature data of the writers and of previous observers.

INTRODUCTION

BRIDGMAN¹ and Boydston² have recently measured the thermal e.m.f. of bismuth crystals of various orientations³ against a reference metal. From these results are deduced by the usual thermodynamic relations, values of the Peltier e.m.f. between the reference metal and a crystal of any orientation or between two crystals of different orientations; likewise the differences in the Thomson coefficients for the two parts of the above combination are deduced. In the investigation described below the Peltier e.m.f. against copper and the Thomson coefficient of bismuth crystals, covering most of the possible orientation range, were measured directly. Two sets of crystals were used, the first for measurement of Peltier coefficient, the other for all the other measurements, which included determination of specific resistance, mean thermoelectric power (between 0° and 100°C) against both copper and constantan, and the Thomson effect. From such data it should be possible to test the validity of the Voigt-Thomson symmetry relation for the directly observed Peltier e.m.f. and Thomson coefficient and to make comparison with the indirectly determined values of these same quantities.

APPARATUS AND EXPERIMENTAL METHOD

The method for determining the Peltier e.m.f. is essentially that of Caswell,⁴ or Barker.⁵ The two thermo-junctions (Cu-Bi and Bi-Cu) are isolated

¹ P. W. Bridgman, (a) Proc. Amer. Acad. of A. and S. **61**, 101 (1926); (b) Proc. Amer. Acad. of A. and S. **63**, 351 (1929).

² R. W. Boydston, Phys. Rev. **30**, 911 (1927); also gives reference to earlier work.

³ Orientation is used as usual to define the angle between the length of the specimen and the principal crystallographic axis, which for bismuth is perpendicular to the plane of best cleavage.

⁴ A. E. Caswell, Phys. Rev. **33**, 379 (1911).

⁵ H. C. Barker, Phys. Rev. **31**, 321 (1910).

from each other by placing them in separate Dewar flasks each containing the same amount of calorimetric fluid, a heating coil, a stirrer, and a copper-constantan thermocouple. See Fig. 1 (a). Current from the battery B_2 may be passed in either direction around the Bi-Cu circuit. The purpose of the heating coils is made clear below. By obvious manipulations of switches S_1 and S_2 it is possible to read the temperature in either flask, or to detect a very minute difference in temperature between the flasks. The heating coils, L and R , are wound of No. 36 constantan wire on thin mica sheets, while the leads, which go through the surface of the liquid and through holes in the flask covers, are of No. 2 constantan. The calorimetric fluid is "Finol," a light oil of low specific heat and high mobility. The amount contained in each

Fig. 1. Diagram of apparatus and electrical connections.

flask is about 150 cc. Stirring is done by glass propellers (not shown in Fig. 1) running at the rate of about 1 r.p.s.

The construction of the two bismuth copper junctions, in which the effect is measured, is apparent from the vertical section shown in Fig. 1(b). The two bismuth portions are parts of one crystal rod cut in two. The two ends adjacent to the cut are used to form the two Bi-Cu junctions in the flasks. The copper is No. 6 wire of commercial grade. The bismuth-copper connections are made without solder by fusing the bismuth directly to the copper, using zinc chloride as a flux. To take a reading a known constant current is sent in one direction through the bismuth-copper circuit. Heat is absorbed at the junction where current passes from bismuth to copper. To compensate for this loss of heat (and for the generation of heat at the other junction) current is passed through the appropriate heating coil. This current is con-

tinually so regulated that the flasks show no temperature difference. In about an hour no further adjustment is necessary. The reading of A_1 is then recorded. The current in the main (bismuth-copper) circuit is then reversed, but kept at the previous value, and the procedure above repeated. Caswell has shown that in this case the Peltier e.m.f. is given in volts by

$$\pi = \frac{i_R^2 R + i_L^2 L}{4I}$$

in which i_R , i_L = current (amperes) in right and left heaters, respectively; R , L = resistance (ohms) of right and left heaters respectively; I = current (amperes) in main circuit. This relation is valid provided the following conditions are satisfied.

1. The heat capacities of the two flasks and their contents are the same. This condition was met by making the two as nearly identical as possible.

2. The rate of loss of heat from each flask must be approximately the same. This was tested from time to time during the investigation and found to be satisfactory.

3. The temperature difference between the flasks and their surroundings must be small. The oil in the flasks never exceeded 2°C above room temperature at the end of any run.

For measuring the Thomson coefficient the method of Nettleton,⁶ as modified by Ware,⁷ was used. Measurements of the same specimen made on Ware's apparatus and the writers' agree well. The resistance of each crystal with one end at about 0° and the other at about 100°C is a necessary datum for determining the Thomson coefficient, and from it the specific resistance (at 48.5°C) can be computed. To do this the average cross section of a crystal is found from its measured mass and length, and assumed density (9.78 gm/cm³). The crystals were from 6 to 10 cm long and from 5 to 10 mm² cross sectional area.

With the temperature gradient established along a crystal the thermal e.m.f. was measured with a potentiometer. The reference metal is copper, since the ends of the specimen were fused or soldered to copper blocks. Dividing this e.m.f. by the temperature difference gives the mean thermoelectric power. This is approximately the thermoelectric power at the mean temperature, 48.5°C. The thermoelectric power against constantan was measured in a similar fashion.

The two sets of bismuth crystals were grown by drawing them from a crucible full of molten bismuth. This method and the apparatus have been described by Linder.⁸ The modifications in the procedure mentioned by Boydston and by Hoyem⁹ and Tyndall were also followed. The crystals of

one set (for Peltier Effect) were 30 cm long and from 2.5 to 3.0 mm in diameter. The others have been described above. The material used was Mallinckrodt C. P. bismuth with the following analysis:¹⁰

Zn 0.01%	Cu 0.00%	Fe 0.00%
Pb 0.00%	As 0.000%	Ag 0.04%

RESULTS AND DISCUSSION

Measurements of Peltier e.m.f. against copper were made on fourteen single crystals ranging in orientation from 16° to 90°. For a majority of the crystals five readings were taken. For two, however, six readings were taken, while for three crystals, only four were taken. The arithmetic mean of all the readings on one specimen is the adopted value. The results are shown graphically in Fig. 2, in which the observed Peltier e.m.f. in millivolts is plotted

Fig. 2. Peltier e.m.f. as function of orientation angle.

(circles) against the square of the cosine of the orientation angle. By substituting in $\pi = Te$, in which $T = 300^\circ\text{A}$ and e is the mean thermoelectric power (at 48.5°C) against copper,* previously mentioned, it is possible to obtain values of the Peltier e.m.f. Values obtained in this way are plotted (as crosses) in the same figure. Before plotting, each value has been arbitrarily reduced by 5 millivolts, since any constant difference between the two sets of data can readily be ascribed to the use of different samples of reference metals (a copper block in one case and a copper wire in the other). These two curves are probably in agreement within experimental error. Such plots should yield straight lines to satisfy the Voigt-Thomson symmetry relation.

¹⁰ The bismuth used by Boydston had this same stated analysis. The omission of Ag 0.04% is due to an oversight on his part. It seems certain, however, that the content of Ag in the crystals used in this investigation must be much less than 0.04%. This point is considered later.

* The value of e at 27°C should be used, of course, but it was not determined and probably does not differ much from the value at 48.5°C .

It is obvious that the experimental relation is not linear in either case. Moreover Bridgman¹¹ finds a very similar deviation from linearity for the thermoelectric power (as a function of $\cos^2\theta$) of bismuth crystals against copper, and therefore for the indirectly determined Peltier e.m.f.

TABLE I. Peltier e.m.f. (millivolts) at 27°C.

* Reference metal, M, copper.

** Reference metal, M, constantan.

Table I presents a comparison of previous work with the present, the subscript for Bi being the value of θ . The data in the second and third columns are obtained from the two curves in Fig. 2. To compute Bridgman's values use is made of his empirical formulas¹² for thermal e.m.f. as a function of temperature. The fifth column is obtained from a plot of the observations on thermoelectric power against constantan, previously mentioned. By interpolation in Boydston's Fig. 3 the thermoelectric power (against constantan) is found for 27°C, and from this the values in the last column are easily computed. All the results in this table are found to be in fair agreement, when allowance is made for the fact that in the upper 3 rows of data a different reference metal (or different specimen of the same metal) was used. In the lower two rows the results are typical of bismuth alone and an absolute comparison is allowable. It will be seen that the directly observed values are lower than those computed from $\pi = TdE/dT$. The agreement with this relation is, however, probably as good as is usually obtained. There seems little doubt that the deviation from the Voigt-Thomson symmetry relation is real for the Peltier effect in these crystals. Boydston finds no deviation (at 27°C) and one must conclude that the bismuth used by Boydston differed from ours in spite of having the same stated analysis.

The specific resistance at 48.5°C is plotted in Fig. 3 against $\cos^2\theta$. The line drawn represents Bridgman's latest results, changed to 48.5°C, however, assuming a temperature coefficient of resistivity of 0.0044. With the exception of four points, the results are satisfactory and indicate that the crystals are not badly strained and that the bismuth is very pure, since both strains and impurities seem to affect the specific resistance seriously.¹³ The three high points may be ascribed to slight accidental strains occurring during growth or in the subsequent handling of the crystals. This seems probable also because crystals of intermediate orientations are very easily deformed.

¹¹ Reference 1, (b).

¹² Reference 1, (b), p. 383.

¹³ See discussion by Bridgman, reference 1, (b) pp. 386-389.

Ware has shown for zinc crystals that a deformation which is large enough to raise the specific resistance has a negligible effect on the Thomson coefficient. It might be expected, therefore, that the group of crystals of Fig. 3 would give consistent and satisfactory results for the Thomson coefficient. This is,

Fig. 3. Specific resistance as function of orientation angle.

however, not the case as is evident on reference to Fig. 4, particularly for orientations less than about 50° . These data, moreover, do not provide an adequate test of the Voigt-Thomson symmetry relation. In spite of this an attempt has been made to draw a smooth curve through the observations. Assuming that -8.5 microvolts/ $^\circ\text{C}$ is a reasonably certain value for σ_\perp (i.e. for $\theta = 90^\circ$), it is possible to make comparison with Bridgman's latest data. The values of σ for $\theta = 45^\circ$ and $\theta = 0^\circ$ for a temperature of 48.5°C have

Fig. 4. Thomson coefficient as function of orientation angle.

been computed from formulas deduced by Bridgman¹⁴ from his thermal e.m.f. data. These values are plotted as triangles in Fig. 5. Our curve gives $(\sigma_\perp - \sigma_\parallel) = 43$ microvolts/ $^\circ\text{C}$ at 48.5°C , dependent on a very uncertain extrapolation to $\cos^2\theta = 1$. Boydston's data give $(\sigma_\perp - \sigma_\parallel) = 57.5$, and Bridgman's, 48. At 43.5°C Caswell¹⁵ finds 58 microvolts/ $^\circ\text{C}$ for polycrystalline bismuth, a value considerably in excess of what might be expected from the above stated values for crystals. Laws¹⁶ finds a much lower value, 10 microvolts/ $^\circ\text{C}$.

¹⁶ Laws, Phil. Mag. [6] 7, 560 (1904).

It seems certain, from the investigations of the two writers just mentioned, that a small admixture of tin raises the Thomson coefficient to a very great extent. It therefore seemed desirable to make an analysis of the bismuth. This was done spectroscopically using the spark spectrum and the general procedure of Meggers, Kiess, and Stimson.¹⁷ A small quartz spectrograph was used the dispersion of which was such that the length of spectrum between 3400 and 2600A was 1.5 cm. About 120 spectrograms were taken of three crystals¹⁸ with normal, low, and high Thomson coefficients, respectively, as judged from the curve of Fig. 4. Between exposures a two millimeter piece was clipped from each of the two portions of the crystal between which the spark occurred. All of the spectrograms, except one, were identical and indicated a material of high purity. A very faint and diffuse line which might be the "raie ultime" of silver (3281A) was present in all the spectrograms. No trace of 3383A, another very sensitive silver line, was found. Moreover, comparison of these spectrograms with others taken in this laboratory of bismuth known to contain far less than 0.04 percent Ag, has led to the conclusion that the silver content is much lower than the figure stated in the analysis. Certainly the crystals examined showed no difference from each other and no detectable inhomogeneity in composition between different parts of the same crystal. In the one exceptional case mentioned above one of the electrodes consisted of a portion (one end) which had been accidentally fused and was probably contaminated with solder. Several lead and tin lines were easily identified in this spectrogram.

In conclusion the writers wish to express their thanks to Prof. E. P. T. Tyndall for suggesting this work and for his advice and interest during its prosecution.

SHATTER OSCILLATIONS, THEIR
NATURE AND THEORY*BY E. H. KENNARD
CORNELL UNIVERSITY

(Received December 30, 1929)

ABSTRACT

Shatter oscillations are an apparently novel type in which the pressure sinks periodically to the minimum value which the liquid can sustain, the liquid mass becoming then porous or "shattered"; they tend to be much slower but more powerful than purely elastic vibrations and the wave-form is very different, pressure impulses alternating with long intervals of quiet. An experimental case is described and the general theory of such oscillations is developed. Further experiments are needed.

AN EXPERIMENT

SEVERAL years ago the writer was privileged to witness some interesting experiments upon liquid oscillations in the plant of the Goulds Pumps Company at Seneca Falls, N. Y., which were of an astonishing and apparently little-known type. It is the purpose of this paper to describe them briefly, together with the theory proposed by the author, in the hope that some physicist may be induced to make a detailed study of the phenomena and so to find out whether the theory is correct and adequate.

In the most interesting experiment a pipe 31 m long and full of water was connected at one end to a tank which contained a considerable mass of water and over it air at a pressure of about 4 atmospheres (the pressure of the atmosphere included). At the other end of the pipe was a small pump with its

Fig. 1. Indicator record showing pressure distribution.

discharge valve removed and its suction valve blocked shut, so that it served merely to "fan" the water with an approximately simple-harmonic motion. A recording gauge recorded the pressure of the water in the pipe at a point near the pump.

Under the circumstances one might expect the water column to oscillate like a "closed organ pipe" (i.e. open only at the tank end, where the pressure must have been sensibly constant); the speed of sound in water in such a pipe being about 1360 m per sec, the fundamental period should be around 0.091 sec. Nothing of the sort was observed. At suitable pump speeds oscillations

*Part of this paper was read before the National Academy of Sciences; an abstract of this part appears in *Science*, 70, 618 (1929).

did occur, and of enormous amplitude, but they were much slower than the slowest possible elastic oscillation, and the distribution of pressure was of the remarkable type shown in Fig. 1, which is copied from one of the actual indicator cards. Isolated "humps" of pressure appeared at intervals, in the figure one every 0.7 second, separated by long quiet intervals during which the pressure seemed to be about zero (certainly below atmospheric); the humps always occurred during discharge strokes of the pump (which are shown by horizontal lines in the diagram, four per oscillation in that case). The maximum pressure was usually around 25–30 atmospheres but in one case it rose to 75 atmospheres before the gaskets blew out of the pump and stopped the experiment.

Now the direction in which to look for an explanation of this phenomenon seems obvious enough. In an ordinary elastic oscillation a compression is followed by an equal rarefaction, but water cannot withstand a tension of 20–30 atmospheres; under special conditions tensions up to 5 atmospheres have been observed, but in practice, according to what appears to be the opinion of engineers, the pressure never sinks below zero (i.e. one atmosphere below atmospheric)—at all events no appreciably lower pressures were ever observed in these experiments, although the indicator was often capable of showing them.

We have, then, a case, apparently new in hydrodynamical theory, of large-amplitude oscillations in a liquid whose pressure cannot sink below a certain critical pressure, p_0 . It was at first naively supposed that under these circumstances large gaps might form in the liquid mass; for instance, in the present case, that the column might break loose from the pump and retreat several feet down the pipe. But a little reflection shows that this cannot happen when the minimum pressure is really quite definite. For in order to form such a gap the layer of liquid on one side or the other of it must at some time experience an acceleration directed away from the incipient gap, and, since by hypothesis the pressure is p_0 in the gap and cannot become less than this in the liquid, no force producing such an acceleration can be developed by pressure differences in the liquid (although it could arise, of course, from gravity in a non-horizontal column, and large gaps could then form). For theoretical purposes the situation might be idealized satisfactorily by assuming that when the pressure sinks to p_0 the elasticity drops discontinuously to zero. What happens in practice, however, must be that the liquid mass does break, at many closely spaced points, in consequence of local inhomogeneities of composition or of state and under the action of cohesive forces, so that the liquid becomes full of small crevices or, as we shall call it, "shattered." We shall study this process a little more closely.

THEORY OF SHATTERING IN A LIQUID COLUMN

The point at which the pressure first sinks to the minimum value, p_0 , must be one where, momentarily,

$$\frac{\partial p}{\partial t} < 0, \quad \frac{\partial u}{\partial x} = -\frac{1}{\epsilon} \frac{\partial p}{\partial t} > 0, \quad (1)$$

in which p =pressure, t =time, ϵ =elasticity, u =particle velocity, x =distance along the column. Continuity being assumed, p will then proceed to reach p_0 at neighboring points and a shattered region will form in which $p=p_0$ and is thus uniform, so that $\partial u/\partial t=0$. In this region, according to (1), $\partial u/\partial x > 0$ (see also below, after Eq. (2)); the liquid will therefore expand at a constant rate through enlargement of the crevices so long as the shattered condition persists. The boundaries of the region, which we shall call "shatter-fronts," advance thru the liquid with a speed V which can easily be calculated. During an interval dt let the shatter-front advance positively a distance Vdt from a point P to P' ; then at the beginning of dt the pressure was p_0 at P and $p_0 + (Vdt) \partial p/\partial x$ at P' , whereas at the end of dt it has risen at P' by an amount, actually negative, $(\partial p/\partial t) dt$ and has now become p_0 ; thus $(Vdt) \partial p/\partial x + (\partial p/\partial t) dt = 0$ and

$$V = -\frac{\partial p}{\partial t} / \frac{\partial p}{\partial x} = \epsilon \frac{\partial u}{\partial x} / \frac{\partial p}{\partial x}. \quad (2)$$

A second and rather peculiar condition for the propagation of the shatter-front arises from the condition that the liquid must be left behind it in an expanding condition (or at least not in a contracting one, since then the pressure would immediately rise above p_0 again). In the same notation, at the beginning of dt let the particle velocities at P and P' resp. be u and $u + (Vdt) \partial u/\partial x$; then at the end of dt the velocity is still u at P (because of the uniformity of pressure), but at P' it has changed by $(\partial u/\partial t) dt$. The condition stated then requires that the final velocity at P' shall exceed that at P , or that $u + (Vdt) \partial u/\partial x + (\partial u/\partial t) dt \geq u$; and, since $\partial u/\partial t = -(1/\rho) \partial p/\partial x$ where ρ is the density and the speed of sound is $c = (\epsilon/\rho)^{1/2}$, we have by (2):

$$k^2 \left(\frac{\partial u}{\partial x} \right)^2 \geq \left(\frac{\partial p}{\partial x} \right)^2, \quad V^2 \geq c^2, \quad (3)$$

where $k = (\epsilon\rho)^{1/2}$. It follows that the shatter-front moves with a speed above that of sound; its progress therefore depends upon conditions in the liquid due to other causes than what may be going on in the shattered region.

In its advance the shatter-front may eventually come to a point where the first of Eqs. (3) is no longer satisfied. It will then turn into a "reconsolidating front" and immediately start back in the opposite direction, for the higher pressures in the adjacent unbroken region will accelerate the liquid toward the shattered region. As the reconsolidating front reaches each point in the shattered region, the crevices suddenly close up and the liquid already present undergoes an impulsive acceleration and compression which give to it both the particle velocity u and the pressure p that obtain on the unbroken side of the advancing front. For convenience let us resolve conditions in the unbroken column as usual into two wave-trains moving in opposite directions; let the unbroken column lie on the left, toward $-x$, and let u_1, p_1 be particle velocity and pressure in the wave-train moving positively and u_2, p_2 the corresponding quantities in the other wave-train. Then by the usual laws for elastic waves

$p_1 = ku_1$, $p_2 = -ku_2$, and at the front $p = p_1 + p_2$, $u = u_1 + u_2$. Here u_1 , p_1 , referring to the "incident" waves, are determined by conditions to the left and can be regarded as known, while u_2 and p_2 can be regarded as referring to waves "reflected" from the boundary of the shattered region and are to be found. Let U = velocity of advance of the reconsolidating front and in the shattered region let u_s = particle velocity and f = degree of shattering or fraction of the space that is empty of liquid, both taken at a point just ahead of the advancing front. Then in time dt the front sweeps over a section PP' of length Udt ; during this time the liquid flowing in at P , of volume $u dt$ per unit of cross-section, must fill up not only the crevice-space $fUdt$ but also the space $(1-f)Udt$ $(p-p_0)/\epsilon$ emptied through compression of the liquid already in the section PP' and the space emptied by the outflow past P' of a volume $u_s dt$ of the shattered column. Hence

$$u = \left[f + (1-f) \frac{p-p_0}{\epsilon} \right] U + u_s. \quad (4)$$

(We assume u/U small so that terms in u^2 or u/U can be neglected, as in the ordinary theory of sound.) During the same interval dt the difference in pressure at the ends of the section PP' must impart to the liquid already in it the additional momentum acquired as its velocity changes impulsively from u_s to u ; whence,

$$p - p_0 = \rho U (1-f) (u - u_s). \quad (5)$$

From these two equations we find:

$$(p - p_0)^2 + \frac{\epsilon f}{1-f} (p - p_0) = k^2 (u - u_s)^2, \quad (6)$$

$$\frac{1}{U^2} = \frac{1-f}{c^2} \left[1 - f + \frac{\epsilon f}{p - p_0} \right] = \frac{1}{c^2} \left[1 + f^2 + f \left(\epsilon \frac{1-f}{p - p_0} - 2 \right) \right]. \quad (7)$$

Equation (6) expresses the "boundary condition" that must hold under these conditions at the junction of shattered and unbroken regions. Eq. (7) gives U , and shows, among other things, that $U < c$ under the conditions assumed, since $\epsilon/(p - p_0)$ will be many times greater than 2.

The reconsolidating front in its turn will disappear upon meeting either a similar front moving in the opposite direction or an obstruction, with resulting final elimination of the shattered region (as a third alternative, of course, it might also be overtaken and destroyed by a fresh shatter-front). When two reconsolidating fronts meet, with pressure and particle velocity p , u in the one moving positively and approaching from the left and p' , u' in the other one, then at the point of meeting these quantities will change impulsively to certain values p_m , u_m . Let us resolve the motion on each side into positive and negative wave-trains, with respective pressures $p_1 = (p + ku)/2$, $p_2 = (p - ku)/2$ on the left, and $p_1' = (p' + ku')/2$, $p_2' = (p' - ku')/2$ on the right. Then, after the two fronts meet, these wave-trains advance as usual and by

their superposition determine subsequent conditions in the liquid; after the lapse of a very short time the trains will overlap a little at the point of meeting and will produce there the following values:

$$p_m = p_1 + p_2' = \frac{1}{2}(p + p') + \frac{k}{2}(u - u'), \quad u_m = \frac{p_1}{k} - \frac{p_2'}{k} = \frac{1}{2}(u + u') + \frac{1}{2k}(p - p') \quad (8)$$

The case in which the reconsolidation front is stopped by an obstruction, such as the closed end of the pipe, can be handled by putting $u_m = 0$ in the last equations and eliminating p' and u' ; this gives the usual impact formula:

$$p_m = p + ku. \quad (9)$$

The extension of the theory just developed to the three-dimensional case is easy, but for completeness we shall sketch it. The boundary of the shattered region is in this case a closed surface which may move either as a shatter-front or as a reconsolidating front, or in part as one and in part as the other; the theory developed above will apply provided we take the x -axis along the normal to the surface, with the single exception that we must also take account of expansion due to the component of particle velocity tangential to the surface. The tangential acceleration vanishes because over the surface $p = p_0$ and is constant. One finds thus as the conditions for the advance of a shatter-front, in the unbroken liquid just ahead of it:

$$\text{div } u > 0, \quad k^2(\text{div } u)^2 = \left(\frac{\partial p}{\partial n}\right)^2, \quad (1'), (3')$$

n denoting distance along the normal to the front (which is also the direction of ∇p), and for V , the speed of advance of the front along its normal:

$$V = -\frac{\partial p}{\partial t} / \frac{\partial p}{\partial n} = \epsilon(\text{div } u) / \frac{\partial p}{\partial n}; \quad V^2 \leq c^2. \quad (2'), (3'')$$

When the boundary starts back through the shattered region as a reconsolidating front, we have as boundary conditions for the determination of p and u in the unbroken liquid,

$$(p - p_0)^2 + \frac{\epsilon f}{1 - f}(p - p_0) = k^2(u_n - u_{sn})^2, \quad (6')$$

in exact analogy with (6), n denoting the component normal to the front, and also, owing to the absence of pressure gradient over the front,

$$u_t = u_{st}, \quad (6'')$$

the t denoting the vector component tangential to the front. These equations are equivalent to three scalar ones and suffice to determine the reflected wave in terms of the variables describing the incident waves and the conditions in the shattered region. The value of U , the speed of advance of the front along its normal, is given as before by Eq. (7).

EXPLANATION OF THE EXPERIMENT

In the light of these theoretical developments the course of the oscillation described at the beginning of the article is believed to be as follows. The enormous gradient implied by the momentary high pressure at the pump sets the water into rapid motion toward the tank; this phase should last about $0.091/4 = 0.023$ sec. Then as the pressure sinks to p_0 a shatter-front sweeps quickly along the pipe and a considerable section of the column becomes shattered and remains so, the crevices widening steadily, for a considerable time. Some photographs of the column taken thru a short glass section of the pipe seemed to confirm the prediction of the theory as to its condition during this phase. Finally, as the reconsolidating front arrives at the pump and the now rapidly moving column is brought to rest, a "water-hammer" results and the high hump of pressure is thereby restored.

Unfortunately the mathematical discontinuity in the equations seems to preclude obtaining any simple solution as an illustrative case. The best method of attack seems to be to start with an assumed hump of pressure and determine the motion of the liquid by approximate methods of calculation. It seems most profitable, however, for such a calculation, rather laborious at best, to be undertaken in conjunction with a repetition of the experiment in which simultaneous pressure records are obtained at several points along the pipe, in order to obtain a complete check on the theory. No projected experiment of this sort is known to the writer at the present moment.

LETTERS TO THE EDITOR

Prompt publication of brief reports of important discoveries in physics may be secured by addressing them to this department. Closing dates for this department are, for the first issue of the month, the twenty-eighth of the preceding month; for the second issue, the thirteenth of the month. Atomic Stability as Related to Nuclear Spin

As is well known, the stability of an ordinary atom nucleus is very great. For example almost head-on collisions between α -particles with velocities greater than $0.055c$ (ten thousand miles per second) with nitrogen or argon nuclei, commonly do not disrupt the nucleus, though it is true that in certain collisions the α -particle adds itself to a nitrogen nucleus and a proton is emitted at high speed. Such a high stability in a body of high positive charge does not seem probable on the basis of electrostatic forces alone, so the existence of powerful forces (partly magnetic) associated with spin and other types of quantized momenta, may be assumed. In the extra-nuclear atom, magnetic moments are associated with both orbital and with spin angular momentum, and the stability is greatest when the resultant of each of these sets of momenta is zero, or if $L=0$ and $S=0$.

The problem may be approached from the standpoint of known nuclear relations. In 1917 the writer assumed the electrons in nuclei to be associated in pairs (J. Am. Chem. Soc. 39, 859 (1917), Phys. Rev. 15, 73 (1920)), and it was also shown (Phil. Mag. 43, 305 (1921)) that in almost all atoms the total number of electrons (the electronic number) is even. In addition the number of protons is in general found to be even. Such pairing suggests the relation of antiparallel spins.

It has been shown (loc. cit.) that all atomic species fall into four classes, if oddness and evenness in the number (N) of nuclear electrons, and the number (P) of protons is used as the basis of the classification. The general stability of the atoms of each class is represented by the abundance in the meteorites, in which the abundance follows very general relations, and on earth, where segregation has been more effective. See table at bottom of page. The numbers in parentheses represent later work in which species of smaller abundance have been detected.

Both the abundance and the number of known species are very much higher for class 1 than for the other classes. In fact the abundance in the meteorites for this class is 19 times that for all of the other three classes. For this class alone the known values of the quantum number i , which represents the resultant angular momentum ($ih/2\pi$), are all equal to zero, while for all of the other three classes all of the known values are greater than zero.

In class 1 the nuclear spins (in units $h/2\pi$) have been found to be zero for helium, carbon 12, oxygen 16, and for those isotopes of zinc and of cadmium which belong to class 1 (have even isotopic number). In class 2 the known values are: Li >0 ; F, $1/2$; Na $\geq 5/2$; Cl, $5/2$; La, $5/2$; Pr, $5/2$; Cs >0 ; I, large; Tl, $1/2$;

Class	N	P	Z	Meteor- ites	Earth	Number species	Nuclear spin number	Examples
1	Even	Even	Even	95.4	87.4	71 (73)	0	O ¹⁶ , C, He, Cd (even isotopes)
2	Even	Odd	Odd	2.1	10.8	33	$1/2$ to $9/2$	F, La, Bi
3	Odd	Odd	Even	2.5	1.8	18 (25)	$1/2$	Cd (odd isotopes)
4	Odd	Even	Odd	0.0	0.0	3	1	N ¹⁴

and Bi, 9/2. In class 3 the odd isotopes of cadmium are supposed by Schüler and Bruck to exhibit a value of 1/2.

Class 4 represents the most unstable of all nuclei, since only three species of this type are thus far known, and all of these have only a minute abundance. The only one of these for which the spin is known is nitrogen 14, for which the spin is 1.

Unfortunately, the interpretation of the nuclear spin in terms of intra-nuclear spins, and possibly of other intra-nuclear momenta, is uncertain, though the present values seem to indicate that only the proton spins are apparent. This seems peculiar in view of the fact that the pairing of the electrons is more apparent than that of the protons. It may be possible that the nucleus is too densely packed to allow an electron spin, but it is also pos-

sible that the present apparent absence of electron spins is fictitious.

It may be assumed that one important factor in nuclear stability is to be found in the relations of the intra-nuclear spins, and also of any other types of angular momentum. Since these relations are unknown it has seemed important to show that all known data indicate that: *In general high nuclear stability is associated with zero nuclear angular momentum (zero spin).* The relations of the atomic species indicate that the limits of stability are related to other quantities, and are a function of the relation between Z and N/P , and of some other variables.

The Unified Field Theory and Schwarzschild's Solution: A Reply

I have read with a great deal of interest Mr. Salkover's criticism (Phys. Rev. 35, 209 (1930)) of my paper on Einstein's unified field theory and the Schwarzschild solution (Proc. Nat. Acad. 15, 784 (1929)). I agree with Mr. Salkover that the expression for the electromagnetic potential which I used in my paper for the calculation of the tensor $V_{\beta\gamma}{}^{\alpha}$ was not correctly copied from the previous paper by Wiener and myself there referred to (Proc. Nat. Acad. 15, 802 (1929): communicated in May, 1929). The expression given in the latter paper of course agrees with that calcu-

lated by Mr. Salkover, and also with the value of the tensor $\Lambda_{\mu\nu}{}^{\sigma}$ reported in my paper. This mistake, while vitiating my results on the Schwarzschild solution, in no way affects our previously announced conclusions, in particular the non-existence in the unified theory of an electrostatic field with spherical symmetry.

Scattering of Light in Sodium Vapor

An artificial chromosphere was constructed in the following manner: Sodium vapor was admitted into a cylindrical glass shell, like the region between the walls of an unsilvered Dewar flask, and a filament was inserted along the axis of the cylinder. The filament is considered to be the photosphere, and the sodium vapor shell the chromosphere. When a spectroscope was directed through the shell of vapor, at right angles to the axis, at the continuous background furnished by the filament, the "Fraunhöfer" lines were observed. When the shell was lowered so only the upper part of the cylinder was in front of the slit, resonance radiation was seen, corresponding to the flash spectrum. It was observed that the D lines appeared in absorption at lower

vapor densities than those for which they appeared in emission.

This is in accord with the work of J. Q. Stewart and the author, (Astrophys. J. January, 1930). The reason for this is not understood. It is probably not due to quenching of resonance radiation by the hydrogen present in the sodium, since kinetic theory calculations indicate that it is necessary to assume effective collision radii of order 10^{-6} cm before a collision frequency is obtained comparable to the unloading time of the $2P$ state of sodium; though the work of Mannkopf (Zeits. f. Physik 36, 315 (1926)) leaves some doubt on this point. Since in the experiments of R. W. Wood (Physical Optics, Pp. 575 et seq.) the vapor density was not

accurately known, his experiments cannot given an answer to this problem. While in the present experiment feeble resonance radiation may have been lost through experimental difficulties, such as reflections from the glass surfaces, yet the result is what one would expect on the assumption that pure scattering is not the only process at work in the production of the cores of "absorption" lines, whereas scattering alone produces the edges.

Further evidences for this assumption are discussed in the paper referred to above. It would be interesting to know whether resonance radiation has even been observed at as low vapor densities as to produce just observable absorption.

The Heat of Dissociation of Oxygen

In a recently written paper on the heat of dissociation of carbon monoxide, the writer has pointed out that the energy of the 1D_2 level in the oxygen atom is 1.3 volts. This value agrees well with the one given recently in Nature by McLennan and Crawford. Since the heat of dissociation of oxygen can be calculated from band spectrum data if the energy of the 1D level is known, it is proposed here to point out the source of this new value for the 1D level. The resulting heat of dissociation is equal to 5.7 volts and it lies between the limits set by Professor Birge in his Faraday symposium paper.

In the above mentioned paper, reasons were advanced for the correctness of a linear extrapolation of the vibrational levels associated with the F level of CO. Such an extrapolation yields a value of 2.5 volts for the total energy of the products of dissociation from this level. At the time that the paper was written, the writer was not aware of the fact that Fowler and Selwyn had determined the energy of the 1D_2 carbon atom. Consequently the value of 1.3 volts for the energy of the 1D_2 oxygen atom, proposed by McLennan and Crawford, was used to predict a

value of 1.2 volts for the energy of the 1D_2 carbon atom. This however is exactly equal to the value found by Fowler and Selwyn, so that the above work is really independent evidence that the energy of the 1D oxygen atom is 1.3 volts.

The new value of the heat of dissociation of oxygen follows immediately from the theoretical prediction that the products of dissociation from the B level of oxygen are a normal oxygen atom and one in the 1D level. This has already been used by both Herzberg and Birge in their discussions regarding the heat of dissociation of oxygen. Since that total energy in the B level is known exactly and is equal to 7.0 volts, it follows that the heat of dissociation of oxygen is 5.7 volts. It is believed that, in view of the nature of both the present evidence and that of McLennan and Crawford, this low value for the heat of dissociation is correct to within 0.1 volt.

A Remark on Hyperfine Structure

An error which has crept into the literature of the theory of hyperfine structure might easily cause misunderstanding and indeed in some places has already led to incorrect deductions.

The problem is to determine what is the direction of the magnetic field produced at the nucleus by a spinning electron in its orbit. For large values of l the classical theory will give the correct result and elementary considerations show, that the magnetic field has the opposite direction of the mechanical moment l . The field produced by the spin is parallel to the spin-vector s , but for large values of l

may be neglected. This result means that a spinning proton will be in its most stable state when its mechanical moment i is opposite to j , from which follows that the produced hyperfine splitting will be "regular," the lowest level having the smallest total resultant f .¹

It is obvious that the orbital picture can

¹ For the complete classical expression and its quantum mechanical equivalent see L. Pauling and S. Goudsmit, *The Structure of Line Spectra*, Chapter XI, McGraw-Hill, to appear soon.

not be used for an s state, where $l=0$. Here one should use a model that comes nearer to the results of the quantum mechanics. An s state is then a spherically symmetric charge distribution and the spin may be represented by a current distribution within this charge distribution. The result is that the magnetic field at the nucleus is now *opposite* to the spin direction, in complete agreement with the quantum mechanics calculations of Fermi (Nature **125**, 16, 1930). One thus also expects "regular" hyperfine structure if protons interact with an s electron. (For details, especially in more complicated configurations, see S. Goudsmit and R. F. Bacher, Phys. Rev. **34**, 1501, 1929).

Jackson (Proc. Roy. Soc. **A121**, 432, 1928) in his paper on the hyperfine structure of caesium used incorrect results for both s and p states. He assumes his fine structures to be all inverted, which causes his deductions about the nuclear moment of caesium being $\frac{1}{2}$ to be quite uncertain. Also Hargreaves (Proc. Roy. Soc. **A124**, 568, 1929) in his paper dealing with the quantum mechanics treatment of the interaction between nuclear magnetism and the electron orbit, seems to

have adopted this incorrect result when he compares his expressions with the results obtained by Jackson. It must be mentioned here that the derivations of Hargreaves clearly show that the minus sign entering in his final formula must be an accidental error.

Finally the same error occurs in the important papers of White (Phys. Rev. Dec. 1929 and Feb. 1930) and causes his deductions about the origin of the nuclear magnetism to be incorrect.

Actually "inverted" fine structure² occurs in Cd and probably in Li an explanation of which can not yet be given with certainty.

I hope that this letter will prevent further spreading of this unfortunate mistake.

S. GOUDSMIT

Department of Physics,
University of Michigan,
February 12, 1930.

² "Inverted" means here when the fine structure appears as if it were due to a negative particle in the nucleus. Certain fine structures are inverted because of complications in the electron configurations. (See S. Goudsmit and R. F. Bacher, l.c.)

Doublets in the Vibration Spectrum of Cyclohexane

Infra-red and visible absorption spectra and Raman scattered spectra have shown that the C-H bands of organic compounds are often made up of more than one component. In particular the spectrum of cyclohexane is of interest. The writer has already shown that the second, fifth, sixth and seventh members of the C-H anharmonic series* of this liquid are doublets of comparable intensities. By means of the Raman effect the fundamental band has also been shown to be a doublet by Petrikaln and Hochberg, Ganesan and Venkateswaran, and Daure. The writer has thus far failed to resolve the third and fourth members, probably largely because of the relatively great widths of the component lines. In attempting to resolve the third band a recording quartz spectrograph with a slit width equivalent to 0.006μ was used, but only a single broad band was obtained. A Hilger El spectrograph with neocyanine stained

plates was employed when trying to resolve the 0.93μ band. This band occurs in the region of the spectrum for which the plate is relatively insensitive. Considerable halation resulted from an overexposure of the $0.85-0.90\mu$ region for which the plate is very sensitive. Even when the intensity of the spectrum in this region was cut down by placing a cell of neocyanine solution before the slit of the spectrograph, the broad region of absorption near 0.93μ could not be resolved into a doublet. Although no precise measurement could be made upon the center of the band it seems certain that it has a somewhat lower value than 0.93μ which had been previously determined thermally.

In spite of the inability to separate the components of these two bands, the frequency separations of the remaining five are sufficient to permit us to arrive at some interesting conclusions. In the table are shown the wavelength values λ , λ' , their frequencies ν , ν' , the doublet separations $\delta\nu$, the first differences in the frequencies of the members of the separate series $\Delta\nu$, $\Delta\nu'$, and the second differences $\Delta'\nu$, $\Delta'\nu'$. Since it has been necessary to

* Although the term series is used here, we are in reality dealing with an n' progression according to the general theory of band spectra.

assume reasonable data for the doublet structure of the third and fourth bands these have been bracketed in the table.

further supporting this interpretation has been submitted for publication). In that instance it was assumed that the constant

TABLE I.

* 1.20 ± 0.01 and 0.93 ± 0.01 are the values observed thermally for these unresolved bands.

Since the $\delta\nu$ values are not the same for all of the bands the two broad components cannot be regarded as P and R branches of single bands.

Within the limits of certainty of the $\delta\nu$ values we may conclude that there is a linear relation between these values and n . From this we conclude that the coefficients of n differ in the two anharmonic formulas which relate ν and ν' independently to n . Furthermore, it can be seen that $\delta\nu$ will not extrapolate to zero when n equals zero, and from this fact we conclude that a constant term must appear in one or both of the equations. An inspection of the $\Delta\nu'$ and $\Delta'\nu'$ columns of the table indicates that the equation for the components of higher frequency requires no constant term. We are led therefore to the remarkable conclusion that a subtractive constant term must be included in the equation relating the lower frequency components to n . We have then $\nu_n' = a'n - bn^2$; $\nu_n = -c + an - bn^2$; $\delta\nu = c + (a' - a)n$. It is impossible to say whether there is any small change in the b coefficient.

The writer has already pointed out an instance in the case of ammonia in solution in which an additive constant must be included in the formula which relates a set of anharmonic overtones to their fundamental. (Jl. Franklin Inst. 208, 507 (1929). A paper

term is a measure of the energy which goes to change the molecule to a form with slightly greater potential energy. In the present instance we are forced to conclude that a drop in the potential energy of the vibrator which yields the ν_n frequencies supplies the additional energy which the quantum lacks to produce the vibration. The behavior of the molecule in this respect is in a way similar to its behavior when producing an anti-Stokes line in a Raman spectrum. In the latter instance however the energy which the molecule gives up as it drops to a lower quantized level goes to increase the magnitude of the scattered quantum.

The data of the table cannot be used to decide whether we are dealing with a single kind of C-H vibrator which shifts at times to a lesser value of the restoring force, or with two distinct types of C-H vibrators. The writer however still inclines to his previous viewpoint that vibrations of one of the hydrogen atoms bonded to each carbon atom contribute to one component of the doublet series whereas vibrations of the second hydrogen atom contribute to the other component.

Secondary Emission from Metals by Impact of Metastable Atoms and Positive Ions

In studying the positive column of the noble gases, using plane sounding electrodes, some phenomena were observed, which could not be explained by the theory proposed by Langmuir¹ and applied by himself and Mott Smith² to the mercury arc. The simplest in-

terpretation of the observed discrepancies, was to assume a secondary electron emission

¹ Langmuir, G. E. Rev. 26, 731 (1923).

² Langmuir and Mott Smith, G. E. Rev., 27, 449, etc. (1924).

from a negatively charged plane electrode, amounting to from 40 to 50% of the measured current. This value was obtained by comparing the measured current i_m and the current i_c , calculated from the observed thickness of the space-charge layer with the usual equations.³ We have succeeded in proving directly that there is an electron emission from the electrode of that magnitude, and that it is principally due to impact of metastable atoms on the collecting electrode.

A plane circular collecting electrode (Ni) with a guard-ring was placed in the positive column of a neon discharge ($p=0.02$ mm) with hot cathode. At the center of the metal disk was a small hole, and behind this a Faraday box. The arrangement was such that the box was practically completely shielded from the radiation in the discharge. It was thought that a comparison of the ion current coming through the hole with the apparent ion current density on the central disk would give a measure of the secondary electron emission from the latter. Indeed, the chance for a secondary electron liberated in the Faraday box to get out is so small, that the current recorded at the box was supposed to be a pure positive ion current, provided the plate is sufficiently negative with respect to the gas ($-125v$) to keep out all electrons coming from the discharge. The experimental results were much more complicated than expected. Using different arrangements of potentials we proved that neutral particles, diffusing out of the main discharge through the gap between disk and guard-ring, caused a considerable electron emission from the metal parts behind the collector. This suggested that the secondary emission referred to above was due principally to the action of metastable atoms on the collector.⁴

More quantitative results were obtained in the same tube with another arrangement. Opposite to the plane collector with the guard ring, mentioned above, was a small hollow cylindrical one, whose axis was perpendicular to the plane collector. The near end, covered with Ni gauze, was exposed to the discharge, the sides and other end being shielded by glass. This cylinder was movable in the direction of its axis, i.e., perpendicular to the sur-

face of the disk collector. Suppose the cylinder at a potential $V_c = -125v$ with respect to the gas; it is then collecting a certain positive ion current i_c . The potential of the plate, V_p , originally $-75v$ with respect to the gas, is now made more negative and the variation of i_c is studied as a function of V_p . As long as the plate is positive with respect to the cylinder, no secondary electrons from the plate can reach the latter, since in falling through the positive space charge layer on the disk they can only acquire an energy corresponding to V_p . When the potential of the plate reaches V_c , the ion current i_c shows a decrease due to incoming electrons originating in the space charge sheath on the plate. The mean free path of the electrons with a velocity corresponding to V_p depends on the degree of ionization and can be determined experimentally in each case by varying the distance between the cylinder and the plate, all other conditions remaining the same. Knowing the electron mean free path and the secondary electron current at a given distance, the secondary emission from the plate can be computed and is found to be from 40 to 50% of the total current i_p .

When the current voltage curve of the secondary electrons is differentiated, a velocity distribution curve is obtained which shows that most of the electrons have at least an energy corresponding to V_p ; it follows that they must be liberated at the plate or at a very small distance from it. In addition to the energy, acquired in falling through the space charge sheath, they possess energies of a few volts which are probably initial energies of emission. Some velocity distribution curves show that there are also electrons produced in the sheath at some distance from the plate, but only in small numbers. The interpretation proposed earlier⁵ that the electrons are principally due to photoelectric ionization in the sheath has to be given up. The experiments are continued with an improved apparatus to study the influence of different factors on the secondary emission.

Predictions of Manganese Hyperfine Structure

In a recent letter to the Physical Review H. E. White (Phys. Rev., 35, 208, 1930) announces that he has obtained an analysis of the hyperfine structure of the manganese arc spectrum. His letter contains the results for three levels and mentions that he has been able to analyze many more.

With the aid of the theoretical considerations given in a previous paper (S. Goudsmit and R. F. Bacher, Phys. Rev. 34, 150, 1929) it is possible to predict the hyperfine structure for a number of manganese levels from the few data given by White. Here follow the predictions for the separation factors¹ and the total separations:

$3d^5 4s^1 {}^6D$	$J=4\frac{1}{2}$	$A=0.0139$	$\nu\Delta=0.384^2$
	$3\frac{1}{2}$.015	.29
	$2\frac{1}{2}$.016	.25
	$1\frac{1}{2}$.022	.19
	$\frac{1}{2}$.058	.17
4D	$3\frac{1}{2}$	-.011	-.21
	$2\frac{1}{2}$	-.009	-.14
	$1\frac{1}{2}$	-.005	-.05
	$\frac{1}{2}$	+.025	+.08
$3d^5 4s 5s {}^8S$	$3\frac{1}{2}$.020	.40
6S	$2\frac{1}{2}$.022	.33

These predictions are based on the following assumptions and will, therefore, be correct only if the assumptions are.

(a). The $3d$ electrons give no appreciable contribution to the fine structure. The fact mentioned by White, that the $3d^5 4s^2 {}^6S$ level shows no fine structure does not prove that the contribution of the $3d$ electrons will be

¹ The separation factor A is the proportionality constant which one obtains if one applies the interval rule to the splitting up of the level. It is only then strictly a constant when the interval rule holds. The validity of the vector model and of the interval rule for hyperfine structure was for the first time pointed out with certainty in the bismuth spectrum (E. Back and S. Goudsmit, Zeits. f. Physik 43, 321, 1927) it formed in fact the basis for the analysis of its hyperfine structure and the determination of the nuclear moment, later confirmed by the Zeeman effect.

² Value given by White.

small in all other configurations too, though it is probable.

(b). The addition of the $4s$ electron does not affect the resultant spin of the already present $3d$ electrons. This means that in the expression for A ,

$$A = a \cdot (s/S) \cos(s, S) \cdot (g-1),$$

$(s/S) \cos(s, S)$ is equal to $+1/5$ for the 6D and $-1/5$ for the 4D . This is verified by the formulas for the multiplet separations themselves (S. Goudsmit and C. J. Humphreys, Phys. Rev. 31, 960, 1928) in which this same cosine occurs.

The contribution of the $5s$ electron is estimated to be about one tenth of that of the $4s$ electron.

The contribution of a p electron is of a more complicated type and general expressions which I obtained for it can only be applied to a few simple cases. For two electrons, one being in an s state, the complete expression for A becomes:³

$$A = a \frac{1}{2}(g-1) + b \left[(2-g) + \frac{l(l+1)}{2(l-1/2)(l+3/2)} \left\{ \frac{1}{2}(g-1) - 3(2-g)\Gamma/2L(L+1) \right\} \right].$$

The hyperfine structures in Tl II (J. C. McLennan, A. B. McLay, and F. M. Crawford, Proc. Roy. Soc. A125, 570, 1929) and in Cd (H. Schüller and H. Brück, Zeits. f. Physik 56, 291, 1929) are not yet known with enough accuracy to test the second part of this formula.

S. GOUDSMIT

Department of Physics,
University of Michigan,
February 12, 1930.

³ The constants a and b measure the interaction energy of the nucleus with the s electron and the p electron respectively. Unpublished calculations of H. Casimir give for b in a hydrogenic case

$$b = R\alpha^2 Z^3 g(i) / n^3 l(l + \frac{1}{2})(l+1)$$

in which $g(i)$ is the Landé g -value for the nucleus and thus expected to be of the order $1/1840$.

THE PHYSICAL REVIEW

NUCLEAR SPIN AND HYPERFINE STRUCTURE

By H. E. WHITE¹

PHYSIKALISCH-TECHNISCHE REICHSANSTALT, BERLIN

(Received January 27, 1930)

ABSTRACT

Assuming that hyperfine structure in spectral lines has its origin in the coupling of a nuclear spin with electron resultant J , a comparison between gross structure and hyperfine structure is made from the following relation, $\Delta\nu_g/\Delta\nu_f = m_k/4im_e$. For those atomic systems for which the electron configurations show LS or jj coupling, the agreement with the above equation is quite as good as would be expected. For electronic configurations which do not show LS or jj coupling it is doubtful whether such a comparison of gross structure with hyperfine structure can be suitably made. From the meagre data as yet available, one is led to suspect that nuclear spin is due to the last electrons, protons, or both (most probably electrons) added to the nucleus in atomic construction. These electrons should, in accordance with the principles of the wave-mechanics, have a *probability density* spherically symmetrical about the nucleus. The difference between the electrons associated with the nucleus and the outer electrons is that the nuclear electrons carry with them in space quantization the total mass of the atom.

THE splitting up of ordinary energy levels into a number of hyperfine structure components is quite generally attributed to a nuclear angular momentum. Observations indicate that this nuclear spin, whether due to electrons, protons, or to both electrons and protons, carries with it in space quantization the total mass of the nucleus. Assuming the nuclear spin to be a rotation of the nucleus as a whole, Jackson² has derived the following equation for the approximate shift in energy of ordinary energy levels due to nuclear spin.

$$\Delta\nu_g/\Delta\nu_f = m_k/2m_e. \quad (1)$$

Here $\Delta\nu_g$ is a gross or multiplet structure separation, $\Delta\nu_f$ the corresponding hyperfine structure separation, m_e the mass of an electron and m_k the mass of the nucleus. Since this formula was derived for a nuclear spin of $i = \frac{1}{2}$ a quantum of energy, it may be made general for all values of i by replacing the constant 2 in the above equation with $4i$. This gives

¹ National Research Fellow.

² Jackson, Proc. Roy. Soc. A121, 432 (1928).

$$\Delta\nu_a/\Delta\nu_f = m_k/4im_e \quad (2)$$

which for $i = \frac{1}{2}$ reduces to equation (1).

Jackson has shown² that in the simple case of a so called *one electron system*, like caesium, an electron spin doublet separation ($\Delta\nu_a$), for example $^2P_{1/2} - ^2P_{3/2}(6p)$, is to be compared with the hyperfine separation ($\Delta\nu_f$) of one of the terms, 2P . The ratio $\Delta\nu_a/\Delta\nu_f$, as compared with computed values from Eqs. (1) and (2), is in reality in quite good agreement (Table I).

From a discussion with Dr. Schüler³ it appears that the hyperfine structure of $\lambda 5486$, $^3S_1 - ^3P_{0,1,2}$, in singly ionized lithium may be accounted for by assigning an angular momentum, $i = \frac{1}{2}$, to the nucleus of Li.⁷ From the observed hyperfine structure, the $^3S_1(1s2s)$ term and the $^3P_2(1s2p)$ term have normal doublet separations of about 0.60 cm^{-1} and 0.45 cm^{-1} respectively (error $\pm 0.10 \text{ cm}^{-1}$). The splitting up of these terms is shown in Fig. 1. In

Fig. 1.

Fig. 2.

this case of a nucleus and two electrons, it may be shown by the use of Fig. 2 which gross structure and which hyperfine structure separations are to be compared with each other. The left hand vector i , in Fig. 2, may be taken to represent the nuclear angular momentum, $\frac{1}{2}$, of Li,⁷ and j_1 and j_2 may be taken to represent $1s$ and $2p$ electrons respectively. In the space quantization of these three vectors the coupling between j_1 and j_2 produces the gross-structure energy levels, whereas the coupling between j_1 and i and between j_2 and i produces the hyperfine energy levels. For the term 3P_2 of Fig. 1, all three vectors i , j_1 and j_2 , Fig. 2(a), are parallel as shown.⁴ When i is now inverted, to position Fig. 2(b), the shift in energy to the term 3P_2 is observed to be about 0.45 cm^{-1} . Owing to the relative nearness of the $1s$ electron

³ Schüler, Zeits. f. Physik.

⁴ With the apparent need of the new quantum number f to represent an energy level, it is suggested that this quantum number precede the ordinary term designation as a subscript for example, $_{3/2}^3D^0_2$. If the electron configuration is given, it is desirable to include the nuclear spin, for example, $_{7/2}^3S_1$. A radiated hyperfine structure line would be designated, $_{3/2}^3S_1 - _{5/2}^3P^0_2$.

to the nucleus, this shift in energy is almost entirely due to the coupling between j_1 and i . When from $_{5/2}^3P_2$, Fig. 2(a), the vector j_1 is inverted to position Fig. 2(c), the shift in energy to $_{3/2}^1P_1$ is observed to be about -7000 cm^{-1} . The inversion now of i to position $_{1/2}^1P_1$, Fig. 2(d), should produce, although not yet observed, a shift of about -0.4 cm^{-1} . The inverted hyperfine structure in this 1P_1 term follows from the hypothesis that, while the separation arises from the coupling between j_1 and i , space quantization must take place between nuclear spin, i , and electron resultant, J .⁵ The ratio $\Delta\nu_g/\Delta\nu_f$ is given in Table I along with the values obtained for other elements.

Making quite the same arguments given above for lithium, a correlation between gross structure and hyperfine structure may be made for an atomic system having a number of valence electrons, for example, manganese, Mn I. Using again Fig. 2, vector i is taken to represent the nuclear angular momentum $i = 5/2$ of manganese, vector j_1 to represent a $4s$ electron and, vector j_2 to represent the resultant angular momentum of all of the rest of the electrons outside of the nucleus, for example $3d^5$, 5D_4 , of Mn II. With all three vectors parallel as in Fig. 2(a) the atom is in state $^7D_{9/2}(i_{5/2}3d^54s)$. The inversion of vector i to position (b), $^6D_{9/2}(i_{5/2}3d^54s)$, produces a shift in energy of about 0.50 cm^{-1} . An inversion, however of vector j_1 from position (a) to position (c), $^4D_{7/2}(i_{5/2}3d^54s)$, produces a shift in energy of $-6,244 \text{ cm}^{-1}$. The ratio $\Delta\nu_g/\Delta\nu_f = 12,488$ is in quite good agreement with the calculated value 10,100.

In order to account for the observed hyperfine structure of the principal doublet of caesium, Jackson² assigned an angular momentum of $i = \frac{1}{2}$ to the nucleus of caesium. It is interesting to note that the observations are equally well explained by assuming greater values of i . From values of nuclear spin found in other elements $1/2$, $5/2$ and $9/2$, and the last two columns of Table I, excluding Tl and Cd, the value $i = 5/2$ seems to be, although the evidence is not strong, the more probable for caesium.

TABLE I.
A comparison of gross structure with hyperfine structure.

Element	i	Electron Config.	Terms	$\Delta\nu_g$	$\Delta\nu_f$	$\Delta\nu_g/\Delta\nu_f$	$m_k/4im_s$
Li ⁷ II	$\frac{1}{2}$	$1s2p$	$^3P_2^\circ - ^1P_1^\circ$	7,000	0.45	15,555	6,440
Mn I	$2\frac{1}{2}$	$3d^54s$	$^6D_{4\frac{1}{2}} - ^4D_{3\frac{1}{2}}$	6,244	.50	12,488	10,100
Mn I	$2\frac{1}{2}$	$3d^54p4s$	$^8S_{3\frac{1}{2}} - ^6S_{2\frac{1}{2}}$	9,984	.60	16,640	10,100
Cs I	$\frac{1}{2}$?	$6p$	$^2P_{3/2}^\circ - ^2P_{1/2}^\circ$	554	.01	55,400	122,000
Cs I	$2\frac{1}{2}$?	$6p$	$^2P_{3/2}^\circ - ^2P_{1/2}^\circ$	554	.01	55,400	24,500
Cs I	$4\frac{1}{2}$?	$6p$	$^2P_{3/2}^\circ - ^2P_{1/2}^\circ$	554	.01	55,400	13,600
Tl I	$\frac{1}{2}$	$6p$	$^2P_{3/2}^\circ - ^2P_{1/2}^\circ$	7,793	.40	19,480	187,600
Tl II	$\frac{1}{2}$	$6s6p$	$^3P_2^\circ - ^1P_1^\circ$	13,935	3.5	3,980	187,600
Cd I	$\frac{1}{2}$	$5s5p$	$^3P_2^\circ - ^1P_1^\circ$	11,864	.25	47,460	103,000

The ratios $\Delta\nu_g/\Delta\nu_f$, given in Table I for Tl I and Tl II, are decidedly not in agreement with the calculated value 187,600. From Zeeman effect data on $\lambda 3776$ of Tl I⁶ the nuclear spin is quite certainly $1/2$. The enormous hyperfine

⁵ H. E. White, Phys. Rev. 34, 1404 (1929).

⁶ Schüller and Brück, Zeits. f. Physik 56, 291 (1929).

structure separations in Tl II as compared with the small separations found in Tl I are undoubtedly due to the strong coupling between i and the deep penetrating $6s$ electron for Tl II, in contrast with the coupling and penetration of a $6p$ electron in Tl I. In Tl II, it would appear that the difficulty arises in the uncertainty of the coupling between the two valence electrons. Since the terms do not indicate either LS or jj coupling, it is doubtful whether such a comparison of gross structure with hyperfine structure can be suitably made for such cases. It has been interesting to note, however, for all observed hyperfine structure, that the space quantization between electron resultant J and the nuclear spin i always follows the interval rule, i.e., a Ji coupling where the intervals are proportional to $\cos Ji$. The exact form of the constant multiplier of i in equation (2) depends largely upon the distribution of charge causing the nuclear spin. Even with the meagre data as yet available, one is led to suspect that the nuclear spin is due to the last added electrons, protons, or both electrons and protons. From observations electrons alone seem to be the most probable.⁵ These electrons should, in accordance with the principles of the wave mechanics, have a probability density spherically symmetrical about the nucleus and might be thought of as a charged shell over the surface of the nucleus. The difference between the electrons associated with the nucleus and the outer electrons is that the nuclear electrons carry with them in space quantization the total mass of the atom.

The author wishes to take this opportunity to thank Dr. Paschen for his interest in and criticism of this paper.

THE SECOND SPARK SPECTRUM OF ANTIMONY AND A NOTE ON THE FIRST SPARK SPECTRUM OF TIN

BY R. J. LANG

UNIVERSITY OF ALBERTA, EDMONTON, CANADA

(Received January 30, 1930)

ABSTRACT

Some sixty lines of the vacuum spark spectrum of antimony have been classified as transitions between the following terms of Sb III: $(s^25p)^2P$, $(s^26p)^2P$, $(s^26s)^2S$, $(s^27s)^2S$, $(s^28s)^2S$, $(s^25d)^2D$, $(s^26d)^2D$, $(s^24f)^2F$, $(s^25f)^2F$, $(s^25g)^2G$, $(s^26g)^2G$, $(s5p^2)^4P$, 2D , 2S , 2P and $(5p^3)^4S$. Corresponding to the deepest term value an ionization potential of approximately 24.7 volts is calculated. A note on SN II gives the terms 4P and 2S from the $(s5p^2)$ configuration and new value for the terms: $(s^27s)^2S$, $(s^28s)^2S$, $(s^27d)^2D$ and $(s^26f)^2F$.

THE vacuum spark spectrum of antimony has been measured over the range 6600 to 600A and also the Paschen hollow-cathode spectrum from 5200 to 1950A. By means of these two measurements it has been possible to separate the first and second spark spectra rather definitely from one another and thus to arrive at a classification for the latter. Work on the first spark spectrum is now in progress and will be reported on later. The measurements of the vacuum spark spectrum below 2500A were made on a two-meter grating mounted in a vacuum spectrograph giving a dispersion of 4.5A per mm. Above 2000A several instruments were used. The vacuum spark and hollow cathode spectra were measured in Edmonton on a two-meter Rowland grating kindly loaned to the author by Professor Smith. The vacuum spark spectrum was also measured in Michigan by the author using a Hilger E_2 quartz spectrograph made available through the courtesy of the Department of Physics. The author is also indebted to Professor R. A. Sawyer of Michigan for a plate of the vacuum spark in the region from 5300 to 6600A made on a large Hilger glass spectrograph. A few wave-lengths are taken also from Schippers measures given by Kayser.

In a previous report¹ the author gave three multiplets for Sb III all of which turn out to be real but the first one given was improperly classified as $(s^26s)^2S-(s^26p)^2P$. It should have been $(s5p^2)^2S-(s^26p)^2P$. It thus corresponds very satisfactorily to the doublet in As III at 4200A. A paper on As III and Sb III appeared later in the Indian Journal of Physics.²

Some important electron configurations and resultant terms expected in the spectrum of Sb III are as follows:

¹ Lang, Phys. Rev. 32, 737 (1928).

In Table I the terms which have been located together with the empirical term values and separations are given. All of the term values rest upon an arbitrary choice of 64000 cm^{-1} for the value of $(s^25f)^2F_{\frac{3}{2}}$. Experience has shown that one can probably arrive at as good or even better values for the terms by a comparison such as is given in Table II than by the use of a Rydberg formula applied to two P or two S terms such as are available in this instance. The deepest F terms are not absolutely certain since the combination with the deepest normal D terms is not very satisfactory. The same may also be true of the second G terms and the third S terms, the last depending upon one combination only since no others fall within the range of measurements. Hence until some of these terms can be established more certainly it seemed as well to estimate the value of the basic term.

In Table III the intensities of observed combinations are shown and under each intensity the discrepancy between the observed wave-number and the wave-number calculated from the values assigned to the energy levels is given. In Table IV a list of all the lines which have been classified in the spectrum of Sb III is given. Throughout this report all wave-lengths above 2000\AA are given in I.A. (air) below this value in I.A. (vacuum) while all wave-numbers are reduced to vacuum values. Corresponding to the deepest term of this spectrum an ionization potential of 24.7 volts is found.

A NOTE ON SN II

The hollow cathode spectrum of tin was also photographed between 6000\AA and 2000\AA in an endeavor to find more terms from the $(s5p^2)$ con-

figuration. Out of the total of nine terms (4P , 2D , 2S , 2P) arising from this configuration none but 2D had been located.³

The $(s^25p)^2P - (s5p^2)^4P$ multiplet in In I had already been found⁴ and those for Sn II and Sb III were located by the use of the doublet laws. The multiplet in Sn II is taken from the spectrum of the hollow cathode. It occurs but very weakly in the vacuum spark spectrum. That for Sb III is taken from the vacuum spark spectrum and the only abnormality is the weak intensity of one of the lines in this multiplet.

* Green and Loring.

The $(s^25p)^2P - (s5p^2)^2D$ multiplet seems well established in Sn II and Sb III. One peculiarity worth mentioning is that the position of this multiplet in the spectrum of Sn II is almost exactly the same as in Si II⁵. However, there seems little doubt that in Sn II this group has been correctly classified³ for when a tin spark in nitrogen, excited by a 2200 volt transformer joined to the 110 volt A.C. mains, was photographed between 2000A and 1250A but nine tin lines were found including the three lines of this multiplet, and every one of these lines except one (1290.90A) had been classified as arising from transitions involving the deepest 2P levels of the atom of Sn II.

³ Green and Loring, Phys. Rev. 30, 574 (1927).

⁴ Lansing, Phys. Rev. 34, 597 (1929); Sawyer and Lang, Phys. Rev. 34, 712 (1929).

⁵ Fowler, Trans. Roy. Soc. A225, 26 (1925).

In regard to the $(s^25p)^2P - (s5p^2)^2S$ doublet it may be stated that the line (1290.90A) together with another line at 1223.79A which occurs in the vacuum spark, but unable here to pass the fluorite window, have the separation of the deepest 2P terms. There seems little doubt that these two lines represent this doublet as has been suggested.³

The remaining $(s^25p)^2P - (s5p^2)^2P$ multiplet in Sn II has not been located with any certainty. There is one possibility worth mentioning, however. The $(s^25p)^2P - (s^27s)^2S$ doublet³ occurs with too great intensity in the vacuum spark and the 2S term is greater than one would expect. Another pair of weaker lines, one of which had not been resolved from a stronger tin line, probably represent this doublet and the stronger pair represents one-half of the missing multiplet. However, it must be said that there is not complete agreement yet between Sn II and Sb III in regard to these terms of the $(s5p^2)$ configuration and it does not seem possible to obtain this at the present time. When the arc spectrum of indium has been studied below 2000A it should be possible to obtain this agreement. An attempt to do this is now in progress. One or two other minor alterations have been made in the spectrum of Sn II all of which are shown in Table V.

The author takes this opportunity of thanking the Research Council of Canada for a grant to carry on this research.

THE EMISSION SPECTRUM OF BENZENE
IN THE REGION 2500-3000ABY J. B. AUSTIN* AND IAN ARMSTRONG BLACK†
DEPARTMENT OF CHEMISTRY, YALE UNIVERSITY

(Received January 25, 1930)

ABSTRACT

The ultra-violet emission band spectrum of benzene vapor has been observed with a Tesla discharge as a means of excitation. The wave-lengths of over 100 bands lying between 2400 and 3000A have been measured with an accuracy of $\pm 0.5A$. It is found that the measurements are in general in agreement with those of McVicker, Marsh and Stewart. All the bands except the faintest and most diffuse ones may be represented by the following equations:

$$1/\lambda = 37485 + 924m - 161n$$

$$1/\lambda = 37398 + 924m - 162n$$

$$1/\lambda = 37485 - 986m - 162n$$

$$1/\lambda = 37425 - 986m - 162n$$

$$1/\lambda = 36479 - 991m - 162n$$

$$1/\lambda = 36412 - 991m - 162n$$

where m and n are integers.

The evidence supporting the conclusion that the bands are due to benzene and not to some decomposition product is summarized. The applicability of the data to spectroscopic analysis is also discussed.

INTRODUCTION

THE general features of the spectra obtained from the vapor of benzene and its simple derivatives under the excitation of the Tesla discharge have been described by McVicker, Marsh and Stewart,¹ who have designated them as Tesla luminescence spectra to distinguish them from the absorption and fluorescence spectra. The present research was undertaken as an extension of their work; it was hoped, on the purely chemical side, to develop the suggestion made by them that a means of ascertaining the identity and quantity of any impurity present could be elaborated. In this regard it has been shown that such a method would be unwieldy in practice, except perhaps for routine work on a large number of samples; moreover, the number of likely impurities which yield satisfactory spectra under these conditions is rather small. On the other hand, it was felt that more comprehensive data on the Tesla luminescence spectra, particularly on the spectrum of benzene which is noteworthy for the sharpness of its bands and the absence of any continuous background, might be obtained, which with the increased accuracy would lead to some theoretical interpretation of the observed regularities. In this object some success has been achieved and the present work describes the results for benzene; the results for the simple derivatives will be published in the near future.

EXPERIMENTAL METHOD

The methods employed differed from those of McVicker, Marsh, and Stewart in many ways, the most significant difference being the use of much lower pressures of the vapor. They used benzene vapor at pressures as high as 65 mm of Hg and were forced to use a steam jacket to prevent condensation; in the present work the pressures ranged from 0.01 to 0.10 mm which yielded satisfactory results at room temperature. In its final form our apparatus was fitted with internal electrodes whereas the previous practice used external ones. The general scheme for producing and maintaining these low pressures was to place the liquid benzene in a side limb of the discharge tube, to immerse it in liquid air to freeze the liquid to a solid cake, and then to seal the side limb and evacuate the system with a mercury diffusion pump until the residual air was so attenuated that a discharge could not be produced. The liquid air bath was then partially removed to allow the frozen benzene to warm slightly so that its vapor at low pressure could continuously diffuse through the discharge tube to a liquid air trap where it was condensed. In this manner equilibrium between speed of pumping and rate of sublimation was soon established and could be modified to give pressures between the limits of 0.01 and 0.10 mm. This method of maintaining a constant flow of vapor in the tube helped to remove any decomposition products as soon as they were formed and in conjunction with the low kinetic energy, and consequent small molecular disruptive power of the Tesla discharge gave some assurance that the spectrum originated in the benzene molecule. As a further precaution against contamination a new tube and liquid air trap were used for each exposure.

The first attempt to obtain the desired spectrum was made with the so-called "electrodeless" discharge, produced by placing the discharge tube in a helix of stout brass rod through which the current from a 1 KW Thordarson transformer was passed. A few trials sufficed to show that the spectrum obtained under these conditions was not that of the undecomposed molecule, but was due apparently to molecular fragments. Moreover, this discharge was very sensitive to slight fluctuations in pressure; with the pressure above a certain limiting value the free electrons and ions did not seem to attain a velocity sufficiently high to excite the rest of the vapor; with pressures too low the intensity of the glow suffered appreciably. At times this discharge showed a tendency to form a shell adjacent to the inside wall of the tube which electrically shielded the interior and caused a luminescent cylinder to form; the dark core of this cylinder rendered the discharge quite unsuitable for photographing.

It is interesting to note that the exciting coil and discharge tube grew quite warm during the passage of the current through the former; at the end of a run the latter invariably cracked, the cracks following the helix around the tube; whether the rupture of the glass was caused by thermal or electrical strain was not determined.

The next attempt was made with electrodes of lead foil wrapped around a Pyrex tube. This set-up yielded a satisfactory spectrum but endless trouble

was experienced with the breakdown of the glass along the surface between the electrodes. The presence of air streaks in the glass made trouble certain.

Finally it was decided to install internal electrodes, a procedure which had hitherto been regarded as hazardous because of the possibility of excessive decomposition of the vapor. Such electrodes, however, proved the

Fig. 1. Discharge tube.

most satisfactory of all the arrangements tried and in most cases caused no greater decomposition than the other types. This system was used to obtain all the results herein reported. Fig. 1 shows the discharge tube which consisted of a cylinder of Pyrex, *P*, with a quartz window, *W*, sealed on at one end with de Khotinsky cement; the other end was connected to a vacuum

Fig. 2. Electrical connections.

system and a mercury diffusion pump. The electrodes, *T*, were cylinders of aluminum attached to tungsten seals; a side bulb, *S*, held the benzene.

The electrical system is shown in Fig. 2. When properly tuned this circuit gave a potential of about 120,000 volts as estimated from the spark produced between metal points.

SPECTROSCOPIC AND PHOTOGRAPHIC METHODS

In this work two spectrographs were employed:

(a) A Hilger size C quartz spectrograph, giving a photograph 200 mm in length for the range 2100A to 7000A. On this instrument exposures ranging from 3 to 12 hours were made; a plate exposed for 12 hours was used for the final measurements. For comparison, the spectrum of a mercury arc was superposed on the middle of the benzene spectrum with the aid of a reducing stop on the slit.

(b) A Hilger E_1 quartz spectrograph (Littrow mounting) giving a spectrum 140 mm in length for the region 2500A to 3000A. The spectrum of the mercury arc was superposed on these plates as on the others.

All photographs were taken on Eastman 33 plates of a special thin glass so that they could conform to the curvature of the plate holder without danger of breaking. In the earlier stages of the work Nujol and transformer oil were tried as sensitizers but were later discarded since they did not appreciably enhance the intensities of the ultra violet lines and were not deemed of sufficient value to warrant the extra trouble.

The spectra obtained with the smaller instrument extended almost 150A farther into the ultra-violet than those from the larger one; on the latter no bands were measured beyond 2600A while on the former they were recorded as far as 2471A. This difference is probably due to the greater absorption of the thicker quartz prism in the big spectrograph. On the other hand the large Hilger resolved some of the bands and permitted greater accuracy in measurement; hence, to obtain a complete spectrum of considerable accuracy the data obtained with the two instruments have been combined.

WAVE-LENGTH MEASUREMENTS

All plates were measured on a Société Genevoise ruling engine whose ruling mechanism had been replaced by a plate holder and a fixed telescope with cross hair attachment. The screw head was graduated in divisions of 0.005 mm with a vernier which allowed readings to be made to 0.001 mm. Tests on the accuracy of the screw showed that any deviations or flaws in it were negligible compared to other errors. The wave-lengths of the unknown lines were calculated by means of the parabolic interpolation formula:

$$\lambda_i = \lambda_0 + as_i + bs_i^2$$

where λ_0 , a and b are constants determined from the mercury lines² and s_i is the reading of the measuring engine corresponding to the i^{th} line. This formula proved to be as accurate as the observations for ranges of 200A in the lower visible and ultra-violet and involved much less labor than the Hartmann formula. The whole spectrum was covered in overlapping sections of 200A.

Each plate was measured in the center of the spectrum to avoid any error due to curvature of the lines. The further precaution was taken of having

each of us independently measure each plate twice, once when it was run along the measuring engine forward and once backward; in this way each line was approached from both sides. The agreement obtained in these sets of observations was most satisfactory, the difference rarely exceeding $\pm 0.5\text{\AA}$ and in most cases being less than $\pm 0.25\text{\AA}$. The four measurements of each line have been averaged and converted to wave numbers in vacuo.

PREPARATION OF BENZENE

Merck's product was shaken six times with concentrated sulfuric acid; at the end of this treatment no color was imparted to fresh acid. The benzene was then washed successively with concentrated sodium hydroxide, dilute sodium hydroxide, and distilled water, until the final wash water was neutral to litmus. The resulting product was dried over sodium for 25 hours and redistilled from the same. A large fraction came over at a constant temperature and this was taken for use. B. P. 80.0°C at 760 mm Hg pressure.

RESULTS

The general scheme of the bands is shown in the photograph, Fig. 3. The following table gives the average results obtained from the two spectrographs. Lines observed only on the smaller spectrograph are marked with an asterisk. The results of McVicker, Marsh, and Stewart are given for comparison.

While a rough notion of the relative intensities of the bands may be gathered from Fig. 3, a more exact measure for the most prominent band groups is given in the microphotograph, Fig. 4. This was made on a Koch-Goos microphotometer from a plate taken on the large spectrograph. The ratio of length on this curve to length on the plate is 2:1.

It was found that all the principal bands could be accounted for with an accuracy of $\pm 3\text{ cm}^{-1}$ by the following equations:

$$1/\lambda = 37485 + 924m - 161n$$

$$1/\lambda = 37425 - 986m - 162n$$

$$1/\lambda = 37398 + 924m - 161n$$

$$1/\lambda = 36479 - 991m - 162n$$

$$1/\lambda = 37485 - 986m - 162n$$

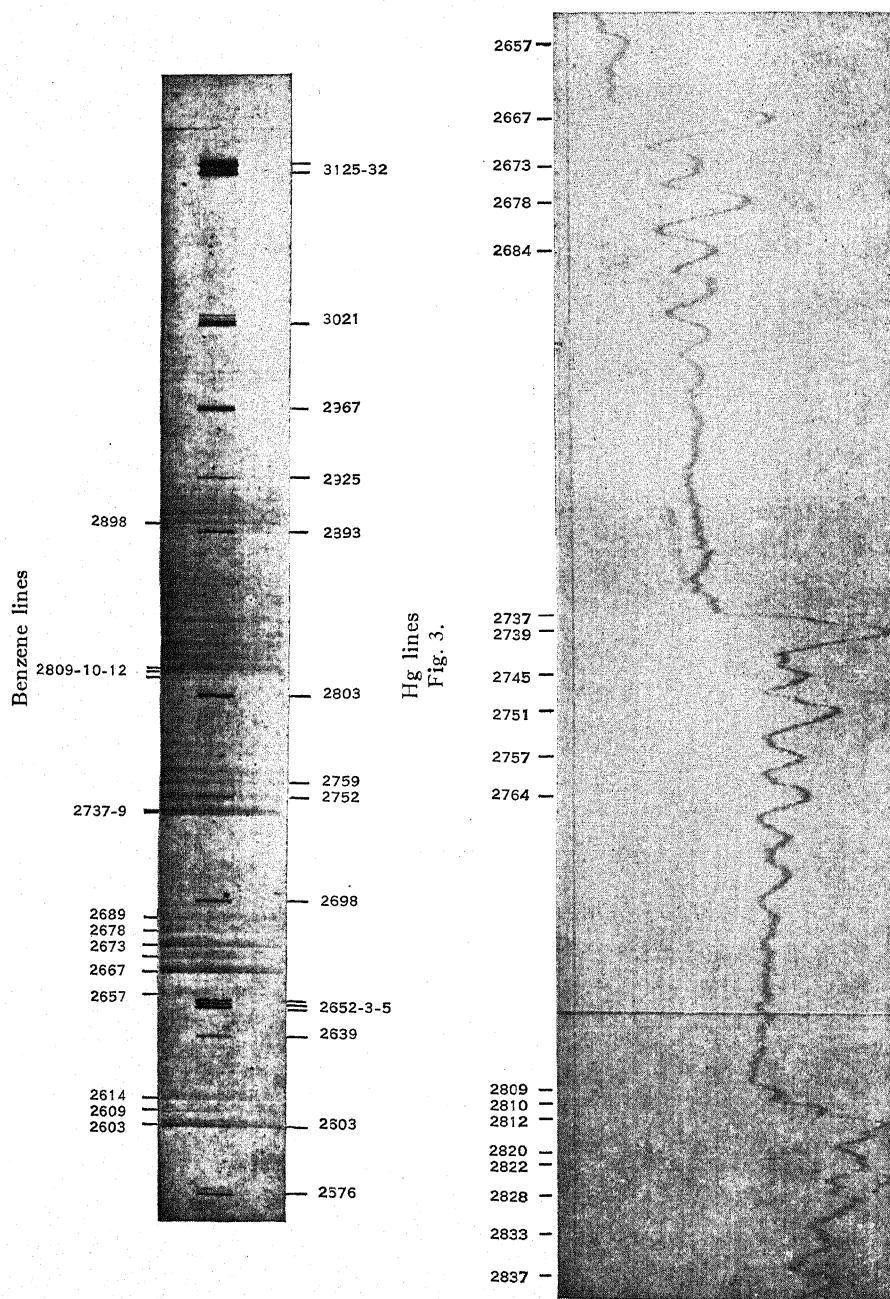

$$1/\lambda = 36412 - 991m - 162n$$

where m and n are assigned integral values. In one band (2667.4) some of the fine structure was observed, the wave-length difference being about $\pm 0.5\text{\AA}$. This agrees with the value reported by Henri³ in the absorption spectrum. It is interesting to note in this connection that the wave-number differences 991 and 162 cm^{-1} appearing in these equations are found also in the Raman spectrum of benzene. It is hoped that before long some definite significance can be attached to these values.

It may be well to review the evidence supporting the assumption that this spectrum originates in the benzene molecule for in spite of all precautions some decomposition did occur. At the end of the 12 hour runs the surfaces of

³ Henri, *Structure des Molecules*, Paris, 1925, p. 109.

the aluminum electrodes were found to be covered with a layer of carbon and the discharge tube showed a very thin film of a shellac-like substance adher-

ing to the walls. However, despite the appearance of these products there is little doubt that the spectrum observed is actually that of benzene. Apart

from the fact that the decomposition products seem non volatile, the following considerations point to the same conclusion.

First, it was observed that conditions which produced the greatest visible decomposition gave spectra of low intensity. Thus, for example, as the pressure is lowered decomposition is decreased while the intensity of the glow is increased. This is just what is to be expected since, for a given energy input, the larger the amount of energy used in molecular rearrangements, the smaller will be the fraction of the total energy as light.

Second, the regularity exhibited by the spectrum seems to militate against any decomposition hypothesis, for this regularity implies a uniformity in the system which produces it; if this system is a benzenoid molecule, its symmetry is easily understood, but if it is produced by some dissociation or rearrangement under the stress of the discharge then it is necessary to postulate an absolute uniformity of decomposition which would be hard to concede from a theoretical view point and would certainly not account for the fact that several decomposition products are actually found.

Aside from these considerations, which involve only the emission spectra, the results can be checked with the spectra in solution. For instance, Dickson⁴ has observed the fluorescence spectrum of benzene in alcohol solution. It is well known that a solvent shifts the spectrum of a substance in solution but this shift is generally a translation of the system as a whole so that the relative positions of the bands remain unchanged. It is found that if 19 units of wave-number are added to the values given by Dickson the broad bands of his spectrum coincide with the principal emission bands which we have observed.

Even more convincing is the agreement between the absorption and emission spectra of the vapor, which prove to have identical band arrangements. The emission spectrum should include the bands found in absorption but the far ultra-violet part of the former is lacking due to the absorption by unexcited benzene molecules in the discharge tube. However, it is found that the most refrangible emission band group coincides with the bands of the red end of the absorption spectrum as determined by Henri.⁵ This arrangement is shown in the following table.

TABLE II.

⁵ Henri, J. de Phys. et Rad. 3, 181 (1922).

This check is sufficient to establish the fact that the carrying structure is the same, and, since no decomposition is to be expected, nor indeed is any found, in the absorption work, it follows that both spectra are due to undecomposed benzene.

The foregoing considerations, in addition to demonstrating that the benzene molecule is the carrier of the spectrum, also indicate a very satisfactory agreement between our work and the known absorption and fluorescence spectra. It may be of interest to conclude with a comparison of our results with those of McVicker, Marsh and Stewart. Taking the results from both spectrographs we have recorded the wave-length of about 110 bands and in addition to more than doubling the known number of emission bands have given evidence of two new band systems in the far ultra-violet. We do not claim to have measured all the bands in the spectrum, however, for in many cases bands could be seen on the plates with the naked eye which were not susceptible of measurement under the microscope. We have also shown that many of the lines reported by McVicker, Marsh, and Stewart are really doublets. A number of our measurements when expressed in wave numbers seem to be about 30 units smaller than those of the corresponding lines in the work of McVicker, Marsh, and Stewart. This is interesting on account of the fact that in the comparison made between their results and Hartley's values for the absorption of benzene approximately 20 units were added to the latter in order to make the regularities coincide.

In conclusion the authors wish to express their thanks to Dr. John Johnston at whose suggestion the work was undertaken, to Dr. A. E. Ruark who gave valuable assistance with the experimental work, to Professor Uhler for much help in the spectroscopic and photographic work and for suggesting the methods of measurement and calculation, to Professor McKeehan who kindly placed the resources of the Sloane Physics Laboratory at our disposal. The authors wish also to thank the Commonwealth Fund for the fellowship which one of them held and without which he would have been unable to undertake this research.

NOTE ON THE THEORY OF THE INTERACTION
OF FIELD AND MATTERBY J. R. OPPENHEIMER
BERKELEY, CALIFORNIA

(Received November 12, 1929)

ABSTRACT

The paper develops a method for the systematic integration of the relativistic wave equations for the coupling of electrons and protons with each other and with the electromagnetic field. It is shown that, when the velocity of light is made infinite, these equations reduce to the Schroedinger equation in configuration space for the many body problem. It is further shown that it is impossible on the present theory to eliminate the interaction of a charge with its own field, and that the theory leads to false predictions when it is applied to compute the energy levels and the frequency of the absorption and emission lines of an atom.

THE relativistic theory of the interaction of electrons and protons with each other and with the electromagnetic field has been developed in two papers.¹ The theory is developed in close analogy to the corresponding classical theory: the field is on the one hand determined by the configuration of the charges; and the motion of the charges is affected by the field. The interaction between two charges is not then, on this theory, expressed directly as a function of the configuration of the charges, but as the effect on each of the charges of the field induced by the other. On the classical theory this procedure involves grave difficulties, because each charge reacts also with its own field. The proper energy of this interaction is, for point charges infinite; and it depends upon the motion of the charge. On the classical theory one tried to avoid this difficulty by ascribing to the elementary charges a finite size; but it was not possible to carry through the theory in a way that was not completely arbitrary; nor was it possible to make the work relativistically invariant. One of the purposes of the present paper is to see in how far these difficulties persist in the quantum theory, and in what measure they render impossible the application of the theory.

We may recapitulate briefly the main points of divergence between the present quantum theoretic treatment and the classical theory. In the first place the state of the matter is here represented, not by a trajectory, but by a wave function. Further, the Hamiltonian for the matter is that derived from Dirac's linear wave equation, and not from the quadratic wave equation which would follow from the classical relativistic Hamiltonian. Finally, both the material waves and the electromagnetic waves are quantized, the matter

¹ W. Heisenberg and W. Pauli, *Zeits. f. Physik* 56, 1 (1929); *ibid.* in press. The second of these two papers is referred to in this work as LC. I am greatly indebted to Professor Heisenberg and Professor Pauli, not only for the opportunity of seeing their work before its publication, but also for their very valuable criticism and advice.

to make the particles satisfy the exclusion principle, the field to make the quanta satisfy the Einstein-Bose statistics. This procedure leads to a formal difficulty; for the fourth Maxwell equation

$$\operatorname{div} \mathbf{E} - 4\pi\rho = 0 \quad (1)$$

is inconsistent with the quantum conditions, according to which there are functions of the electromagnetic potentials which do not commute with $\operatorname{div} \mathbf{E}$ but which must commute with the charge density. The two papers of Heisenberg and Pauli are distinguished chiefly by different methods of resolving this difficulty. In the former paper new terms were added to the fourth Maxwell equation to make the new equation consistent with the quantum conditions; in obtaining physical results these terms were to be made to vanish. In the second paper a much more satisfactory method has been used, which takes advantage of the fact that the left hand side of (1) is a constant of the motion for all systems involving matter and radiation; and it is shown that this constancy follows from the gauge invariance of the Hamiltonian for all such systems. The solution of the dynamical problem thus reduces to finding a wave function for the coupled system of field and matter, which makes the Hamiltonian for the coupled system a diagonal matrix, and which in addition makes the left hand side of (1) vanish. The wave function has thus to satisfy not only the Hamiltonian wave equation, but also a series of wave equations which express the fact that (1) is satisfied at all points in space. It is from this set of wave equations that we shall start in this paper; we shall write them first in the form given in LC Eq. (68), in which the wave function is taken as a function of the Cartesian coordinates

$$q_P = (q_P^{(1)}, q_P^{(2)}, q_P^{(3)}); P = 1, 2, \dots, N$$

and spin variables

$$\sigma_P; P = 1, 2, \dots, N$$

of the N particles in the system, the number of quanta

$$M_{r\lambda}$$

of frequency

$$\nu_r$$

vector of propagation $\mathbf{K}_r = (K_r^1, K_r^2, K_r^3)$; $K_r = \nu_r/c$ and polarization λ , and finally a third set of variables P_{r3} , which are essentially the constant components of the electric field parallel to the vectors of propagation \mathbf{K}_r . We shall first show that it is possible to eliminate the P_{r3} 's from the wave equations in such a way that (1) is automatically satisfied. The reason why this is possible is that the condition (1) determines $\operatorname{div} \mathbf{E}$ precisely—instead of determining only the relative probabilities of different values of $\operatorname{div} \mathbf{E}$,—when the configuration of the charges is known, so that the values of the P 's so determined can be put at once into the Hamiltonian. When this is done the variables Q_{r3} canonically conjugate to the P 's must disappear from the Hamiltonian, since otherwise the Hamiltonian would not be consistent with (1);

we shall show that this is in fact the case, and then proceed to an investigation of the resulting Hamiltonian.

It should be observed that the wave functions must satisfy, in addition to the wave equations in configuration space, the condition that they be antisymmetric in all the electrons of the system, and antisymmetric in all the protons of the system. Only wave functions satisfying these conditions are to be considered in this paper; and it will therefore be unnecessary to indicate the antisymmetry of the wave functions explicitly. The fact that electrons and protons satisfy the exclusion principle is largely irrelevant to the difficulties discussed in this work; for these difficulties persist even in the one-electron problem. On the other hand it is to be hoped that the resolution of the errors in the present theory will make the heuristic postulate of the exclusion principle unnecessary.

We shall look for a solution of the wave equation in which both wave function and characteristic values are expanded in powers of v/c . It has already been shown by Breit² that, when the interaction of the particles may be treated as small, and radiation processes may be neglected, that these interaction terms give a contribution to the energy of the system, which, in second order in v/c , agrees with that computed from Breit's equation.³ We shall not retain the assumption that the interaction terms are small, and shall show, somewhat more generally, that when the proper energy terms are systematically neglected, the characteristic energy levels and the wave function are determined by Breit's equation. This equation is, of course, not relativistically invariant; and it takes no account of radiation processes. In order to remedy these defects one must retain the proper energy terms; and we shall show that it is then possible to make a *formally* satisfactory theory to give the shape and position of all spectral lines, and the energy of the normal state. The theory, is, however, wrong, since it gives a displacement of the spectral lines from the frequency predicted on the basis of the nonrelativistic theory which is in general infinite. This displacement arises from the infinite interaction of the electron with itself; this interaction depends upon the state of the material system; and the difference in the energy for two different states is not in general finite. Thus the present theory gives no more than the nonrelativistic theory of Jordan, Klein and Wigner.⁴ It seems improbable that Breit's equation gives the energy levels of an atom correct to second order terms in v/c ; but we shall see that there is ground for supposing that it does give the separation of the fine structure levels correctly in this order. On the other hand the displacement in the frequency of the spectral lines which arises from the proper energy should be of the second order in v/c , and is thus larger than the natural line breadth, which is of the third order; and on the present theory it is not possible to compute this displacement. We shall return later to a consideration of these difficulties.

² G. Breit, Phys. Rev. 34, 553 (1929).

³ Breit, *ibid.*, Eq. (6).

⁴ P. Jordan and O. Klein, Zeits. f. Physik 45, 751 (1927). P. Jordan and E. Wigner, *ibid.* 47, 631 (1928).

1. The condition that the left hand side of (1), regarded as an operator on the wave function ψ of the variables

$$q_P, \sigma_P, M_{r\lambda}, P_{r3}$$

shall make the wave function vanish at every point in space, gives a series of wave equations

$$I \quad C_r \Psi = \left[P_{r3} + \sum_P e_P v^{r0}(q_P) \right] \psi(q_P, \sigma_P, M_{r\lambda}, P_{r3}) = 0$$

which must hold for all values of the K_r consistent with the boundary conditions. Here the v^{r0} are functions defined in LC (54):

$$v^{r0}(q_P) = \frac{2}{\pi} (ck_r^3 L^3)^{-1/2} \sin \pi k_r^{(1)} q_P^{(1)} \sin \pi k_r^{(2)} q_P^{(2)} \sin \pi k_r^{(3)} q_P^{(3)} \quad (2)$$

Here L is the length of the fundamental cube, or Hohlraum, and is taken finite in LC to avoid the introduction of a continuous manifold of normal coordinates; in all our results we shall make L become infinite. Furthermore the Hamiltonian for the coupled system, regarded as an operator on the same wave function, gives the wave equation

$$\begin{aligned} II \quad & \left\{ -E + \sum_r \left[\sum_{\lambda=1,2} M_{r\lambda} \hbar \nu_r + \pi \nu_r P_{r3}^2 \right] + \sum_{P=1}^N \left[\frac{\hbar c}{2\pi i} (\alpha^P \text{grad}_P) + m_P \alpha_0^P c^2 \right] \right\} \psi \\ & + \left\{ \sum_{P=1}^N [e_P A_0^0(q_P) + e_P (\alpha^P \cdot A^0(q_P))] \right\} \psi \\ & + \left\{ i \sum_r \sum_{\lambda=1,2} \sum_{P=1}^N \mu_P^{r\lambda} [(M_{r\lambda} + 1)^{1/2} \Delta_{r\lambda}^{-1} - M_{r\lambda}^{1/2} \Delta_{r\lambda}] \right\} \psi \\ & + \left\{ \sum_r \sum_{P=1}^N \mu_P^{r3} Q_{r3} \right\} \psi = (+H - E) \psi = 0. \end{aligned}$$

Here A_0^0 is the external scalar potential, and A^0 the external vector potential; and $\Delta_{r\lambda}$ is an operator which transforms $M_{r\lambda}$ into $M_{r\lambda} - 1$, and leaves all other variables unchanged; the α^p 's are operators which operate only on σ_p , and are derived from the Dirac matrices $\alpha_{p\sigma}^i$ by the definition

$$\alpha_i^P F(\sigma_P) = \sum_{\rho_P} \alpha_{\sigma_P}^i \rho_P F(\rho_P); \quad \alpha_0^P F(\sigma_P) = \sum_{\rho_P} \alpha_{\sigma_P}^0 \rho_P F(\rho_P).$$

Further the Q_{r3} are canonically conjugate to the P_{r3} so that

$$[P_{r3} Q_{r'3}] = \frac{\hbar}{2\pi i} \delta_{rr'} \quad (3)$$

Finally the functions $\mu_P^{r\lambda}, \mu_P^{r3}$ are defined in LC (59):

$$\mu_P^{r3} = e_P c \left(\frac{\nu_r}{2} \right)^{1/2} \sum_{i=1}^3 \alpha_i^P v_i^{r3}(q_P)$$

$$\mu_P^{r\lambda} = e_P c \left(\frac{\hbar}{2\pi\nu_r} \right)^{1/2} \sum_{l=1}^3 \alpha_l^P v_l^{r\lambda}(q_P); \lambda=1,2 \quad (4)$$

$$v_l^{r\lambda}(q_P) = \left(\frac{8}{L^3} \right)^{1/2} F_{l\lambda}^r \cos \pi k_l q_P^{(l)} \sin \pi k_{l'} q_P^{(l')} \sin \pi k_{l''} q_P^{(l'')};$$

$$l=1,2,3.$$

$$\lambda=1,2,3.$$

The square matrix $F_{l\lambda}^r$ is given by the scheme

$$\begin{array}{c|ccc} & \lambda = & 1 & 2 & 3 \\ \hline l & & & & \\ 1 & & \epsilon_2^r / (\epsilon_1^2 + \epsilon_2^2)^{1/2} & \epsilon_1 \epsilon_3 / (\epsilon_1^2 + \epsilon_2^2)^{1/2} & \epsilon_1 \\ 2 & & -\epsilon_1 / (\epsilon_1^2 + \epsilon_2^2)^{1/2} & \epsilon_2 \epsilon_3 / (\epsilon_1^2 + \epsilon_2^2)^{1/2} & \epsilon_2 \\ 3 & & 0 & -(\epsilon_1^2 + \epsilon_2^2)^{1/2} & \epsilon_3 \end{array} \quad (5)$$

where the ϵ_l^r 's are the direction cosines of the vector \mathbf{K}_r . It should be observed that

$$\frac{\hbar c}{2\pi i} (\mathbf{a}^P \cdot \text{grad}_P) e_P v^{r0}(q_P) = \frac{\hbar}{2\pi i} \mu_P^{r3}. \quad (6)$$

This equation, together with (3), shows that

$$[HC_r] = 0 \quad (7)$$

for all r , so that all the C_r 's are constants of the motion. The equations I and II are those given⁵ in LC (68).

From I we see that the wave function must be singular in the P 's. We may avoid the use of singular functions by making a contact transformation from the variables P to Q , and writing the wave function as:

$$\psi(q_P, \sigma_P, M_{r\lambda}, Q_{r3}).$$

For we may then solve (3) by taking

$$P_{r3} = \frac{\hbar}{2\pi i} \frac{\partial}{\partial Q_{r3}}.$$

If now we set

$$\psi(q_P, \sigma_P, M_{r\lambda}, Q_{r3}) = e^{-2\pi i / \hbar \sum_r \frac{1}{p} \sum_p e_p v^{r0}(q_p) Q_{r3}} \phi(q_P, \sigma_P, M_{r\lambda}, Q_{r3}) \quad (8)$$

the equations I give us

$$\frac{\partial \phi}{\partial Q_{r3}} = 0 \quad (9)$$

for all r so that

$$\phi = \phi(q_P, \sigma_P, M_{r\lambda}).$$

⁵ In LC (68) the A 's are dropped,

Further the Hamiltonian II becomes

$$\begin{aligned}
 & e^{-2\pi i/\hbar} \sum_r \sum_P e_P v^{r0}(q_P) Q_{r3} \left\{ -E + \sum_r \left[\sum_{\lambda=1,2} M_{r\lambda} \hbar v_r + \pi \nu_r \sum_{P,P'}^N e_P e_{P'} v_0^{r0}(q_P) v^{r0}(q_{P'}) \right] \right. \\
 & + i \hbar \sum_r \sum_P \nu_r e_P v^{r0}(q_P) \frac{\partial}{\partial Q_{r3}} - \frac{\hbar^2}{4\pi} \sum_r \nu_r \frac{\partial^2}{\partial Q_{r3}^2} + \sum_P \left[\frac{\hbar c}{2\pi i} (\alpha^P \text{grad}_P) + m_P c^2 \alpha_0^P \right] \\
 & - c \sum_r \sum_P e_P (\alpha^P \text{grad}_P) v^{r0}(q_P) Q_{r3} + \sum_P e_P [A_0^0(q_P) + (\alpha^P \cdot A^0(q_P))] \\
 & + \sum_r \sum_P \mu_P r^3 Q_{r3} + i \sum_r \sum_{\lambda=1,2} \sum_P \mu_P r^\lambda [(M_{r\lambda} + 1)^{1/2} \Delta_{r\lambda}^{-1} \\
 & \left. - M_{r\lambda}^{1/2} \Delta_{r\lambda}] \right\} \phi(q_P \sigma_P M_{r\lambda}) = 0.
 \end{aligned} \quad (10)$$

The terms in Q drop out because of (6); the terms in $\partial/\partial Q$ give nothing because of (9). The equations I and II thus reduce to the single system

$$\begin{aligned}
 & \left\{ -E + H_0 + \sum_{r\lambda} M_{r\lambda} \hbar v_r + i \sum_{r\lambda P} \mu_P r^\lambda [(M_{r\lambda} + 1)^{1/2} \Delta_{r\lambda}^{-1} - M_{r\lambda}^{1/2} \Delta_{r\lambda}] \right\} \phi = 0 \\
 & H_0 = \sum_P \left\{ \frac{\hbar c}{2\pi i} (\alpha^P \text{grad}_P) + m_P c^2 \alpha_0^P + \rho_P [A_0^0(q_P) + (\alpha^P \cdot A^0(q_P))] \right. \\
 & \left. + \pi \sum_{P'} \sum_r e_P e_{P'} \nu_r v^{r0}(q_P) v^{r0}(q_{P'}) \right\}.
 \end{aligned} \quad (11)$$

It is this system which we must now investigate.

The terms

$$G(q_P, q_{P'}) = \sum_r \pi \nu_r v^{r0}(q_P) v^{r0}(q_{P'})$$

may readily be evaluated,⁶ and give for $L \rightarrow \infty$

$$G(q_P, q_{P'}) \rightarrow -\frac{1}{2r_{PP'}}; \quad r_{PP'} = |\mathbf{q}_P - \mathbf{q}_{P'}|. \quad (12)$$

The terms for p and p' different give the electrostatic interaction of the two particles; the terms for $p=p'$ give the infinite electrostatic proper energy of the particles; on the present theory it is not possible, as it was on the non-relativistic theory,⁴ to eliminate these terms; the physical ground for this impossibility has already been indicated, and lies in the fact that the field acting on any particle is the sum of the fields induced by all particles; it is a consequence of the principle of superposition for the field. These electrostatic proper energy terms do not, however, interfere with the application of the theory, since they are constants, and may be dropped from (11) without altering the form of the wave function. We shall find other infinite proper

⁶ W. Heisenberg and W. Pauli, *Zeits. f. Physik* 56, 1 (1929). Eq. (115); G. Breit, reference 2 Eq. (57). Breit has independently evaluated the P_{rs} terms in the Hamiltonian; and I am much indebted to him for informing me of his result.

energy terms in the course of the work; but these will turn out not to be constants, but to depend upon the configuration of the system; dropping them does alter the form of the wave function.

If we now neglect the coupling between matter and the light quantum field the wave equation reduces to

$$\left[-E + H_0 + \sum_{r\lambda} M_{r\lambda} h\nu_r \right] \phi = 0 \quad (13)$$

and for the case that no quanta are present we have

$$\left\{ -E + \sum_P \left[\frac{hc}{2\pi i} (\alpha^P \cdot \text{grad}_P) + m_P c^2 \alpha_0^P + e_P [A_0^0(q_P) + (\alpha^P \cdot A(q_P))] \right] - \sum_{PP'} \frac{e_P e_{P'}}{2r_{PP'}} \right\} \phi(\sigma_P, q_P) = 0. \quad (14)$$

We shall show that the terms which we have neglected in (12) are small of the order $(v/c)^2$; and by neglecting other terms of the same order, (13) can be considerably simplified. For consider first the equation

$$\left\{ -E + \sum_P \left[\frac{hc}{2\pi i} (\alpha^P \cdot \text{grad}_P) + m_P c^2 \alpha_0^P \right] \right\} \phi = 0. \quad (15)$$

For N -free uncoupled particles. If we choose all matrices $\|\alpha_{\sigma_P}^i\|$ of the form

$$\begin{pmatrix} 0 & 0 & b & a \\ 0 & 0 & c & d \\ \bar{b} & \bar{c} & 0 & 0 \\ \bar{a} & \bar{d} & 0 & 0 \end{pmatrix} \quad (16)$$

and all the $\|\alpha_{\sigma_P}^0\|$ of the form:

$$\begin{pmatrix} +1 & 0 & 0 & 0 \\ 0 & +1 & 0 & 0 \\ 0 & 0 & -1 & 0 \\ 0 & 0 & 0 & -1 \end{pmatrix} \quad (16)$$

and satisfying of course

$$[\alpha^{\mu,P} \alpha^{\nu,P'}] = 0 \text{ for } P \neq P'; [\alpha^{\mu,P} \alpha^{\nu,P}] = 2\delta_{\mu\nu} \quad (17)$$

then any $\phi(\sigma_P)$ in which n of the σ_P 's have either of the values 3 or 4 will be small compared with any of the ϕ 's for which all of the σ_P 's have the values 1 or 2 of the order $(v/c)^n$. Now the terms

$$- \sum_{PP'} \frac{e_P e_{P'}}{2r_{PP'}} \quad e_P A_0^0(q_P)$$

in (14) do not involve the α^P 's, while the terms

$$e_P (\alpha^P \cdot A(q_P))$$

are small of the order v/c ; thus as v/c is made to vanish, all the solutions of (14) vanish except those for which all the σ_p 's have the values 1 or 2; and (14) reduces to

$$\left[-E + \sum_P \left\{ m_P c^2 + e_P A_0^0(q_P) - \frac{\hbar^2}{8\pi^2 m_P} \Delta_P - \sum_{P'}' \frac{e_P e_{P'}}{2r_{PP'}} \right\} \right] \phi(\sigma_P q_P) = 0 \quad (18)$$

for all σ_p 's = 1 or 2 and

$$\phi(\sigma_P q_P) = 0 \text{ for any } \sigma_P = 3 \text{ or } 4$$

which is the Schroedinger equation for the N -body problem.⁷ It would thus be possible to take (18) as the starting point for our systematic solution of (11) in powers of v/c . We shall not do this, however, as it would complicate the analysis, and lead to no new results. We shall thus give up the assumption that the α 's are written in the form (16), and take for our zero'th approximation to (11), the solutions of (14).*

2. We may write the equations (11) *seriatim*:

$$\sum_{r\lambda} M_{r\lambda} = M = 0; (-E + H_0)\phi = -i \sum_{r\lambda P} \mu_P^{r\lambda} \phi(1_{r\lambda}); \quad \phi = \phi(0_{r\lambda}) \quad (11.1)$$

$$M=1 \quad \left\{ \begin{aligned} (-E + \hbar\nu_r + H_0)\phi(1_{r\lambda}) &= +i \sum_P \mu_P^{r\lambda} \phi - \left[i \sum_{r'\lambda'} \sum_P \mu_P^{r'\lambda'} \phi(1_{r\lambda}, 1_{r'\lambda'}) \right] \\ &- 2^{1/2} i \sum_P \mu_P^{r\lambda} \phi(2_{r\lambda}) \end{aligned} \right. \quad (11.2)$$

$$M=2 \quad \left\{ \begin{aligned} &(-E + \hbar(\nu_r + \nu_{r'}) + H_0)\phi(1_{r\lambda}, 1_{r'\lambda'}) = +i \sum_P [\mu_P^{r\lambda} \phi(1_{r'\lambda'}) \\ &+ \mu_P^{r'\lambda'} \phi(1_{r\lambda})] - i \sum_{r''\lambda''} \sum_P \mu_P^{r''\lambda''} \phi(1_{r\lambda}, 1_{r'\lambda'}, 1_{r''\lambda''}) \\ &- 2^{1/2} i \sum_P [\mu_P^{r\lambda} \phi(2_{r\lambda}, 1_{r'\lambda'}) + \mu_P^{r'\lambda'} \phi(1_{r\lambda}, 2_{r'\lambda'})] \end{aligned} \right. \quad (11.3)$$

$$\left\{ \begin{aligned} &(-E + 2\hbar\nu_r + H_0)\phi(2_{r\lambda}) = +2^{1/2} i \sum_P \mu_P^{r\lambda} \phi(1_{r\lambda}) \\ &- i \sum_{r'\lambda'} \sum_P \mu_P^{r'\lambda'} \phi(2_{r\lambda}, 1_{r'\lambda'}) - 3^{1/2} i \sum_P \mu_P^{r\lambda} \phi(3_{r\lambda}) \end{aligned} \right. \quad (11.4)$$

etc.

Now for fixed r , and fixed K_r ,

$$\mu_P^{r\lambda} = 0(c^{-1/2})$$

whereas

$$\nu_r = 0(c).$$

⁷ It is possible to write the two component wave equation when the magnetic interactions are retained up to the order $(v/c)^2$, as has been shown by Breit, reference 2.

* We shall not make explicit use of the fact that the α 's are in the form (16); we shall, however, retain the assumption that the α 's are small of the order v/c , to obtain $\mu_P^{r\lambda} = 0(c^{-1/2})$.

Thus we should expect $\phi(1_{r\lambda})$ to be small of the order $c^{-3/2}$, $\phi(1_{r\lambda}, 1_{r'\lambda'})$ to be of the order c^{-3} , and so on, and we should try to find a solution of (11) of the form

$$\begin{aligned} E &= E^{(0)} + E^{(1)} + E^{(2)} \dots \\ \phi(M_{r\lambda}) &= \phi^{(0)}(M_{r\lambda}) + \phi^{(1)}(M_{r\lambda}) \dots \end{aligned} \quad (19)$$

with

$$\begin{aligned} E^{(n)} &= 0(c^{-n}) \\ \phi^{(n)}(M_{r\lambda}) &= 0(c^{-n-3/2M}). \end{aligned}$$

It should be observed that in general there will be certain frequencies for which $\phi(1_{r\lambda})$, $\phi(1_{r\lambda}, 1_{r'\lambda'})$ etc. will not converge uniformly for $c \rightarrow \infty$; and that for these frequencies the expansions (19) will be illegitimate. The frequencies for which this convergence is non-uniform are those for which

$$+E - \sum_{r\lambda} M_{r\lambda} h\nu_r$$

is a characteristic value of the homogeneous equations

$$(H_0 - \lambda)\phi = 0. \quad (20)$$

Such frequencies will not occur if (20) has no solutions for $\lambda < E$, i.e. if the material system is in a normal state; but in general the expansions (19) must be modified; we shall return to this modification later, and shall see that it gives a satisfactory theory of the absorption and emission of radiation; but for the present we shall assume that the atom is in a normal state, so that (19) is justified.

On the present theory there is no normal state for the matter, because states of infinite negative energy are possible; one may in fact show that, on the present theory, Dirac jumps to such states from states of positive energy, jumps in which the energy and momentum lost by the matter are taken up by the field, are not only possible, but infinitely probable. But that the theory should predict this is a token of an error in the theory; and since the Dirac jumps do not seem to be *directly* responsible for the difficulties with which we are, in this work, most concerned, we shall for the present neglect them.

We shall first give a complete solution for the case that we drop all proper energy terms, for the case, that is, that in all double sums of the form

$$\sum_{PP'} F(q_P, \sigma_P, q_{P'}, \sigma_{P'})$$

we may set the terms with p equal to p' equal to zero. This solution is not unique beyond terms of the second order in v/c ; for in the higher orders it is no longer possible uniquely to separate proper energy and interaction energy. But we may readily obtain a possible solution:

$$\phi(M_{r\lambda}) = \prod_{r\lambda} \left[\frac{-i \sum_P \mu_P r\lambda}{h\nu_r} \right]^{M_{r\lambda}} \phi \quad (21)$$

where

$$\left[-E + H_0 - \sum_{r\lambda} \sum_{PP'} \frac{\mu_P^{r\lambda} \mu_{P'}^{r\lambda}}{h\nu_r} \right] \phi = 0. \quad (22)$$

For if we put these values, for example, in (11.2) we get

$$\begin{aligned} & \frac{+i \sum_P \mu_P^{r\lambda}}{h\nu_r} \left[-E + H_0 - \sum_{r'\lambda'} \sum_{PP'} \frac{\mu_P^{r'\lambda'} \mu_{P'}^{r'\lambda'}}{h\nu_{r'\lambda'}} + h\nu_r \right] \phi \\ & + \frac{i}{h\nu_r} \left[H_0, \sum_P \mu_P^{r\lambda} \right] \phi = i \sum_P \mu_P^{r\lambda} \phi. \end{aligned} \quad (23)$$

Now in

$$\sum_P [H, \mu_P^{r\lambda}] = \sum_{PP'} \left[\left(\frac{hc}{2\pi i} (\alpha^P \cdot \text{grad}_P) + m_P c^2 \alpha_0^P + e_P (\alpha^P \cdot A(q_P)) \right), \mu_P^{r\lambda} \right] \quad (24)$$

and in

$$\sum_{PP'} \mu_P^{r'\lambda'} \mu_{P'}^{r'\lambda'}$$

we may put

$$\sum_{PP'} \rightarrow \sum'_{PP'}$$

so that

$$\sum_P [H, \mu_P^{r\lambda}] = 0 \quad (25)$$

and (11.2) is satisfied. In a similar way it may be shown that all the equations (11) are satisfied.

We may evaluate the terms

$$\sum_{r\lambda} \frac{\mu_P^{r\lambda} \mu_{P'}^{r\lambda}}{h\nu_r} = e_P e_{P'} \frac{c^2}{2\pi} \sum_{ll'} \alpha_l^P \alpha_{l'}^{P'} \sum_{r\lambda} \frac{v_l^{r\lambda}(q_P) v_{l'}^{r\lambda}(q_{P'})}{\nu_r^2}$$

in (22) by observing that for $l \neq l'$

$$\sum_{r\lambda} \frac{v_l^{r\lambda}(q_P) v_{l'}^{r\lambda}(q_{P'})}{\nu_r^2} = \frac{\partial}{\partial q_{l'}^{l'}} \frac{\partial}{\partial q_P^{l'}} F(q_P q_{P'}) ; \Delta_P F = \frac{\pi}{c^2 r_{PP'}}$$

and

$$\sum_{r\lambda} \frac{v_l^{r\lambda}(q_P) v_l^{r\lambda}(q_{P'})}{\nu_r^2} = \frac{-\pi}{2c^2 r_{PP'}} - \frac{\partial^2}{\partial q_P^{l_P} \partial q_{P'}^{l_P}} F(q_P, q_{P'})$$

so that

$$\sum_{r\lambda} \frac{\mu_P^{r\lambda} \mu_{P'}^{r\lambda}}{h\nu_r} = \frac{-e_P e_{P'}}{4} \left\{ \frac{(\alpha^P \cdot \alpha^{P'})}{r_{PP'}} + \frac{(\alpha^P \cdot \mathbf{r}_{PP'}) (\alpha^{P'} \cdot \mathbf{r}_{PP'})}{r_{PP'}^3} \right\} \quad (27)$$

This gives for ϕ_0

$$\left\{ -E + H_0 + \frac{1}{4} \sum_{PP'} \frac{e_P e_{P'}}{r_{PP'}^3} [(\alpha^P \cdot \alpha^{P'}) r_{PP'}^2 + (\alpha^P \cdot \mathbf{r}_{PP'}) (\alpha^{P'} \cdot \mathbf{r}_{PP'})] \right\} \phi = 0 \quad (28)$$

This is the equation used by Breit.³ It is patently not relativistically invariant; this means that the proper energy terms are not invariant, and forces us to

retain these terms, at least in part. Furthermore, we have not, in the deduction of (28), used the fact that the atom is in its normal state; in spite of this there is no sign, in the solution, of processes involving the emission or absorption of radiation; for these processes arise from the interaction of the particles with their own field. We have, therefore, to consider the solution of (11) when the proper energy is not neglected; the retention of these terms will preserve the invariance of the theory, and give us an account of radiation processes, but it leads to results in contradiction with experiment; it makes the validity of (28), even to the second order in v/c , doubtful.

3. We can readily find a solution of the form (19) when E^0 and ϕ^0 correspond to a normal state for the matter; but we cannot find this solution in closed form; nor is there an equation in configuration space, corresponding to (28), for ϕ . If we put (19) in (11.2) etc. we get

$$\phi^{(0)}(1_{r\lambda}) = i \sum_m \frac{b_{0m}^{r\lambda} \phi_m^{(0)}}{h\nu_r + E_m^{(0)} - E_0^{(0)}}; \left\{ \begin{array}{l} b_{0m}^{r\lambda} = \sum_p \int \cdots \int dq_1^{(1)} \cdots dq_N^{(3)} \\ \left[\sum_{\sigma' \cdots \sigma N} \bar{\phi}_{\sigma'}^{(0)} \mu_P^{r\lambda} \phi_{\sigma}^{(0)} \right] \\ (H_0 - E_m^{(0)}) \phi_m^{(0)} = 0 \end{array} \right. \quad (29)$$

and further

$$\begin{aligned} \phi^{(0)}(1_{r\lambda}, 1_{r'\lambda'}) &= - \sum_{mn} \frac{b_{0m}^{r\lambda} b_{mn}^{r'\lambda'} \phi_n^{(0)}}{[h\nu_r + E_m^{(0)} - E_0^{(0)}][h(\nu_r + \nu_{r'}) + E_n^{(0)} - E_0^{(0)}]} \\ &\quad - \sum_{mn} \frac{b_{0m}^{r'\lambda'} b_{mn}^{r\lambda} \phi_n^{(0)}}{[h\nu_{r'} + E_m^{(0)} - E_0^{(0)}][h(\nu_r + \nu_{r'}) + E_n^{(0)} - E_0^{(0)}]} \quad (30) \\ \phi^{(0)}(2_{r\lambda}) &= - 2^{1/2} \sum_{mn} \frac{b_{0m}^{r\lambda} b_{mn}^{r\lambda}}{[h\nu_r + E_m^{(0)} - E_0^{(0)}][2h\nu_r + E_r^{(0)} - E_0^{(0)}]} \cdot \text{etc.} \end{aligned}$$

Further $E_{(0^1)}$ and $\phi_{(0^1)}$ vanish, and

$$\begin{aligned} E_0^{(2)} &= - \sum_{r\lambda} \sum_m \frac{|b_{0n}^{r\lambda}|^2}{h\nu_r + E_m^{(0)} - E_0^{(0)}} \\ \phi_0^{(2)} &= \sum_{r\lambda} \sum_m \sum_{n=0} \frac{b_{0m}^{r\lambda} \bar{b}_{mn}^{r\lambda} \phi_n^{(0)}}{[h\nu_r + E_m^{(0)} - E_0^{(0)}][E_n^{(0)} - E_0^{(0)}]} \end{aligned}$$

Moreover $\phi^1(1_{r\lambda})$, $\phi_{(0^3)}$ and $E_{(0^3)}$ vanish, and

$$\phi^{(2)}(1_{r\lambda}) = i \sum_{r'\lambda'} \sum_{mk} \sum_{n \neq 0} \frac{b_{0m}^{r'\lambda'} \bar{b}_{mn}^{r'\lambda'} b_{nk}^{r\lambda} \phi_k^{(0)}}{[h\nu_{r'} + E_m^{(0)} - E_0^{(0)}][h\nu_r + E_k^{(0)} - E_n^{(0)}][E_n^{(0)} - E_0^{(0)}]} \quad (32)$$

$$\begin{aligned} E_0^{(4)} &= - \sum_{r\lambda} \sum_{r'\lambda'} \sum_{mk} \sum_{n \neq 0} \frac{b_{0m}^{r'\lambda'} \bar{b}_{mn}^{r'\lambda'} b_{nk}^{r\lambda} \bar{b}_{k0}^{r\lambda}}{[h\nu_{r'} + E_m^{(0)} - E_0^{(0)}][h\nu_r + E_k^{(0)} - E_n^{(0)}][E_n^{(0)} - E_0^{(0)}]} \\ &\quad \text{etc.} \end{aligned}$$

The terms

$$-E_0^{(3)}\phi^{(0)}(1_{r\lambda})$$

and

$$-i \sum_P \sum_{\lambda' r'} \mu_P^{r' \lambda'} \phi^{(0)}(1_{r\lambda} 1_{r' \lambda'}) - 2^{1/2} i \sum_P \mu_P^{r\lambda} \phi^{(0)}(2_{r\lambda})$$

in the equation for $\phi^{(3)}(1_{r\lambda})$ cancel, so that

$$\phi^{(3)}(1_{r\lambda}) = 0$$

and

$$\phi_0^{(5)} = 0, \quad E_0^{(5)} = 0.$$

The expansion for $E^{(0)}$ and $\phi^{(0)}$ can be continued, and only terms of even order in v/c appear.

It will be observed that the interaction terms in (31)

$$- \sum_{r\lambda} \sum_m [h\nu_r + E_m^{(0)} - E_0^{(0)}]^{-1} \left\| \int \bar{\phi}_n^{(0)} \mu_P^{r\lambda} \phi_0^{(0)} d\mathbf{q} \right\| \left\| \int \phi_n^{(0)} \mu_{P'}^{r\lambda} \phi_0^{(0)} d\mathbf{q} \right\| \quad (33)$$

$$\left[\text{we write } \int d\mathbf{q} \text{ for } \int \dots \int dq_1^{(1)} \dots dq_N^{(3)} \sum_{\sigma' \dots \sigma_N} \right]$$

differ from those computed for the second order from (28):

$$- \sum_{r\lambda} \sum_m (h\nu_r)^{-1} \left\| \int \bar{\phi}_n^{(0)} \mu_P^{r\lambda} \phi_0^{(0)} d\mathbf{q} \right\| \left\| \int \bar{\phi}_n^{(0)} \mu_{P'}^{r\lambda} \phi_0^{(0)} d\mathbf{q} \right\| \quad (34)$$

It is possible to express

$$\sum_{r\lambda} \frac{\mu_P^{r\lambda} \mu_{P'}^{r\lambda}}{h\nu_r + E_m^{(0)} - E_0^{(0)}}$$

in terms of the confluent hypergeometric functions, but the expressions are too complicated to be suitable for calculation.

The proper energy terms

$$- \sum_{r\lambda} \sum_P \sum_m \frac{\left| \int \bar{\phi}_m^{(0)} \mu_P^{r\lambda} \phi_0^{(0)} d\mathbf{q} \right|^2}{h\nu_r + E_m^{(0)} - E_0^{(0)}} = - \sum_{r\lambda P m} T_{0m,P}^{r\lambda}$$

do not exist, although both

$$\sum_{r\lambda} T_{0m,P}^{r\lambda}$$

and

$$\sum_m T_{0m,P}^{r\lambda}$$

converge; for large ν_r ,

$$\sum_m T_{0m,P}^{r\lambda} = 0(1)$$

and for large E

$$\sum_{r\lambda} T_{0m,P}^{r\lambda} = 0(1).$$

The energy level of the normal state is thus infinitely displaced by the interaction of the particles with the field; the question which we have now to consider is whether or not the energy differences between two states are displaced by a finite or an infinite amount.

In order to answer this question we must treat the case of energies which do not correspond to a normal state for the matter; and we have to modify (19), and take account of the emission of radiation by the system. And for this purpose it is convenient to make the dimensions L of the Hohlraum infinite, because that makes the physical interpretation of the solution more immediate. For then ν_r becomes continuous and we may normalize the $v_i^{r\lambda}(q_p)$ to the intervals $\Delta\nu\Delta\omega$, where $\Delta\omega$ is the element of solid angle of the unit vector ϵ_r . Furthermore we may treat here, to simplify the writing, the case that E corresponds to the first excited state of the atom, so that there is only one energy E_0 lower than E for which (20) is soluble.

We define the energy of the normal state by

$$E_0 = E_0^{(0)} + E_0^{(2)} + E_0^{(4)} \dots \quad (35)$$

where $E_0^{(2)}$ and $E_0^{(4)}$ are given by (31) and (32), and we define the corresponding wave function

$$u_0 = \phi_0^{(0)} + \phi_0^{(2)} + \phi_0^{(4)} \dots \quad (36)$$

where $\phi_0^{(2)}$ is given by (31). We can then extend this definition formally to obtain the energy and wave function of excited states:

$$\begin{aligned} E_m &= E_m^{(0)} + E_m^{(2)} + E_m^{(4)} \dots ; \\ E_m^{(2)} &= - \int d\nu_r \int d\omega_r \sum_{\lambda} \sum_n \frac{|b_{mn}^{r\lambda}|^2}{h\nu_r + E_n^{(0)} - E_m^{(0)}} \\ u_m &= \phi_m^{(0)} + \phi_m^{(2)} + \phi_m^{(4)} \dots \text{etc.} \end{aligned} \quad (37)$$

But in the expressions for $E_m^{(2)}$ etc, and $\phi_m^{(2)}$ etc, the integrals over ν are now improper, and we have to displace the path of integration around the singularities. This is equivalent to replacing

$$\frac{1}{h\nu + E_n^{(0)} - E_m^{(0)}} \text{ for } E_n^{(0)} < E_m^{(0)}$$

by

$$\frac{1}{h\nu + E_n^{(0)} - E_m^{(0)}} \pm i\pi\delta(h\nu + E_n^{(0)} - E_m^{(0)}) \quad (38)$$

and then taking the principal value of the integrals over ν . Then in general all the E_m 's except E_0 are complex. We now transform the $\phi(M_{r\lambda}, q_p\sigma_p)$ by the formulae

$$\phi(M_{r\lambda}, m) = \sum_{\sigma_P} \int \cdots \int dq_1^{(1)} \cdots dq_N^{(3)} u_m(q_P, \sigma_P) \quad (39)$$

$$\phi(M_{r\lambda}, q_P, \sigma_P)$$

and introduce

$$\mu_{mn}^{r\lambda} = \sum_{\sigma_P} \int \cdots \int dq_1^{(1)} \cdots dq_N^{(3)} \bar{u}_m \mu_P^{r\lambda} u_n. \quad (40)$$

Then if the $\phi(M, m)$ satisfy the equations, which follow from (11):

$$(-E + E_m)\phi(0, m) = -i \int d\nu_r \int d\omega_r \sum_{\lambda} \sum_P \mu_{0m, P}^{r\lambda} F_1(\omega_r, \lambda) \delta\left(\nu_r + \frac{E_0 - E}{h}\right) \\ - \int d\nu_r \int d\omega_r \sum_{\lambda} \sum_P \mu_{nm, P}^{r\lambda} \int d\nu_r' \int d\omega_r' \sum_{\lambda'} \sum_{P'} \mu_{0n, P'}^{r'\lambda'} F_2(\omega_r, \omega_r', \nu_r', \lambda, \lambda') \delta\left(\nu_r + \nu_r' + \frac{E_0 - E}{h}\right) + \cdots \quad (41)$$

$$\phi(1_{r\lambda}, 1m) = i \sum_{P_n} \mu_{nm, P}^{r\lambda} \phi(0, n) \left\{ \frac{1}{-E + h\nu_r + E_m} + \frac{i\pi\delta_{m0}}{h} \delta\left(\nu_r + \frac{E_m - E}{h}\right) \right\} \\ + F_1(\omega_r, \lambda) \delta\left(\nu_r + \frac{E_m - E}{h}\right) - i \sum_P \int d\nu_r' \int d\omega_r' \sum_{\lambda'} \mu_{0m, P}^{r\lambda} \\ F_2(\omega_r', \omega_r, \nu_r', \lambda, \lambda') \delta\left(\nu_r + \nu_r' + \frac{E_0 - E}{h}\right) \cdots \quad (42)$$

$$\phi(1_{r\lambda}, 1_{r'\lambda'}, m) = i \sum_{P_m} \left\{ \mu_{nm, P}^{r'\lambda'} \phi(1_{r\lambda}, n) + \mu_{nm, P}^{r\lambda} \phi(1_{r'\lambda'}, n) \right\} \\ \left\{ \frac{1}{-E + h(\nu_r + \nu_r') + E_m} \pm \frac{i\pi\delta_{m0}}{h} \delta\left(\nu_r + \nu_r' + \frac{E_m - E}{h}\right) \right\} \\ + F_2(\omega_r, \omega_r', \nu_r', \lambda, \lambda') \delta\left(\nu_r + \nu_r' + \frac{E_0 - E}{h}\right) \cdots$$

where now the functions F are completely arbitrary, then the $\phi(M_{r\lambda}, q_P, \sigma_P)$ satisfy (11); for each choice of these F 's we can obtain a solution of (11). Now the terms

$$\frac{\mu_{nm, P}^{r\lambda} \phi(0, n)}{-E + h\nu_r + E_m} \text{ etc.}$$

give a radiation field which does not extend to infinity; and the terms

$$\frac{\pm i\pi \mu_{nm, P}^{r\lambda}}{h} \phi(0, n) \delta_{m0} \delta\left(\nu_r + \frac{E_0 - E}{h}\right) \text{ etc.}$$

represent outgoing⁸ electromagnetic waves, so that by the choice of the F 's

⁸ P. A. M. Dirac, *Zeits. f. Physik* **44**, 585 (1927).

we may determine the radiation incident upon the system. The simplest case is that in which only quanta of the single frequency

$$\nu = \frac{1}{h}(E - E_0) = \nu_r \quad (43)$$

are incident upon the system, so that all the F 's vanish except

$$F_1(\omega, \lambda).$$

For this case

$$\phi(0, m) = + \frac{i \sum_{\lambda} \sum_P \int d\omega_r \mu_{0m, P}^{\tau\lambda} F_1(\omega, \lambda)}{E - E_m} = \frac{iG_m^{\nu}}{E - E_m}. \quad (44)$$

Now by hypothesis E is to be chosen that only one $E_m - E$, that for $m = 1$, say, is to be small, so that only

$$\phi(0, 1) = \frac{iG_1^{\nu}}{E - E_1} \quad (45)$$

is large. The probability of absorption to this state is thus proportional to

$$\frac{|G_1^{\nu}|^2}{|E - E_1|^2} = \frac{|G_1^{\nu}|^2}{|h\nu + E_0 - E_1|^2} \quad (46)$$

so that the shape of the absorption line is given by

$$\frac{\text{const.}}{\left| \nu + \frac{1}{h}(E_0 - E_1) \right|^2} \quad (47)$$

since G_r^{ν} , varies slowly with ν .

If we evaluate E_0, E_1 to the second order in v/c , and drop the higher terms—and this is equivalent to neglecting transitions in which more than one quantum plays a part—(47) reduces to

$$\frac{\text{const.}}{\left[\nu + \frac{1}{h}(E_0^{(0)} - E_1^{(0)}) + \frac{1}{h}(E_0^{(2)} - \frac{1}{2}E_1^{(2)} - \frac{1}{2}\bar{E}_1^{(2)}) \right] + \frac{1}{4h^2} |E_1^{(2)} - \bar{E}_1^{(2)}|^2} \quad (48)$$

The absorption line is thus of the same shape as that predicted on the basis of the correspondence principle, and that found, for this case, by Dirac³, and the half-breadth of the line is

$$\left| \frac{E_1^{(2)} - \bar{E}_1^{(2)}}{2h} \right| = \frac{\pi}{h} \int d\omega \sum_{\lambda} |b_{01}^{\tau\lambda}|^2 = \frac{1}{4\pi\tau_1} \quad (49)$$

where τ_1 is the natural life time of the state 1.

The center of the absorption line is displaced to the red from $(1/h)(E_1^{(0)} - E_0^{(0)})$ by an amount

$$\begin{aligned} & \frac{1}{h} \left(E_0^{(2)} - \frac{1}{2} E_1^{(2)} - \frac{1}{2} \bar{E}_1^{(2)} \right) \\ &= \frac{1}{h} \int d\nu \int d\omega \sum_{\lambda} \sum_n \left\{ \frac{|b_{1n}^{\lambda}|^2}{h\nu + E_n^{(0)} - E_1^{(0)}} - \frac{|b_{0n}^{\lambda}|^2}{h\nu + E_n^{(0)} - E_0^{(0)}} \right\} \\ &\sim \frac{1}{h} \int d\nu \int d\omega \sum_{\lambda} \sum_n \sum_{PP'} \left\{ \frac{\mu_{1n,P}^{\lambda} \mu_{n1,P'}^{\lambda}}{h\nu + E_n^{(0)} - E_1^{(0)}} - \frac{\mu_{0n,P}^{\lambda} \mu_{n0,P'}^{\lambda}}{h\nu + E_n^{(0)} - E_0^{(0)}} \right\}. \quad (50) \end{aligned}$$

Here the principle values are to be taken for all improper integrals over ν . The terms for $p \neq p'$ are just those to be expected from (33) for the displacement of the energy levels by the magnetic interaction of the particles. The terms

$$\frac{1}{h} \int d\nu \int d\omega \sum_{\lambda} \sum_n \left\{ \frac{|\mu_{1n,P}^{\lambda}|^2}{h\nu + E_n^{(0)} - E_1^{(0)}} - \frac{|\mu_{0n,P}^{\lambda}|^2}{h\nu + E_n^{(0)} - E_0^{(0)}} \right\} \quad (51)$$

must be ascribed to the effect of the interaction of the particle with its own field. They may be compared with the formula obtained⁸ for the same effect by Dirac, who finds a displacement

$$\frac{1}{h} \int d\nu \int d\omega \sum_{\lambda} \frac{|\mu_{01,P}^{\lambda}|^2}{h\nu + E_0^{(0)} - E_1^{(0)}}. \quad (52)$$

There does not appear to be any justification for this result, because in its derivation terms were neglected that are of the same order as those retained. But it is of interest to observe that the integral in (52) exists, and gives a finite displacement of the line of the second order in v/c . This displacement is thus larger than the natural line breadth, which is of the third order. It can be computed⁹ when the u 's are known. Thus for the first Lyman doublet of hydrogen we find the same displacement, in this order, for both components; it turns out to be

$$+ \frac{ch}{32\pi^2 e^2} \frac{1}{\tau_1} = \frac{ch}{32\pi^2 e^2} A_{10}$$

which is about forty times the line breadth. The fact that this term, and the similar terms in (51), are the same, in second order, for the two components of the doublet, suggests that the formulae (33) in which the proper energy is neglected, will give the atomic fine structure splitting correct to the second order.

If we try to compute the displacement from (51), we find that the integrals over ν diverge logarithmically for high frequencies. One can readily

⁹ The calculations of the displacements predicted by the results of Dirac were carried through in collaboration with Harvey Hall; and I am indebted to him for permission to quote them here. One must use the retarded potentials to obtain a convergent integral.

see that this is not the result of the neglect of higher order terms, nor of any of the approximations made in the work. The theory thus leads to the false prediction that spectral lines will be infinitely displaced from the values computed by the Bohr frequency condition. The behavior of the expression (51) calls for some comment. As the formula stands, the integral over ν diverges absolutely; this may be verified by evaluating the terms for a free particle. But the question arises whether it is possible so to rearrange the order of the integration over ν the summation over n , and the two integrations involved in the evaluation of the μ_{mn} 's by (40), that the limit $n \rightarrow \infty$, $\nu \rightarrow \infty$ exists. This cannot be effected by an interchange of the sum over n and the integral over ν ; but there is a procedure which, when the E 's in the resonance denominators of (51) are dropped, does give an absolutely convergent result. This procedure was suggested by Heisenberg, who showed that, if we first perform the integration over ν and ω and the summation over λ , then sum over all the states n of the same energy, then sum these up to some large but finite energy E , take the difference of the two terms for the state (0) and the state (1), then perform the two integrations over the configuration space, and finally allow E to become infinite, the limit $E \rightarrow \infty$ exists, and (51) tends to zero. But if we try to apply this procedure to (51) when the E terms are not dropped, we get for the leading term the divergent result

$$4e_p^2/hc \cdot (E_1^{(0)} - E_0^{(0)})/h \cdot \int^\infty dx/x \quad (53)$$

Nor is there any method for obtaining an absolutely convergent expression for (51). It should be observed that (53) gives us another justification for using (33) to get the fine structure separations correct to the second order.

One can see quite simply that (47) ought not to give a finite line displacement. For consider two states of a free particle; in one let the particle be at rest; in the other let it have the velocity v . Then if the energy of the particle at rest be E , the energy of the moving particle in proper coordinates moving with the particle will also be E . But we know how this energy transforms under a Lorentz transformation; in the original coordinates it will be

$$E\beta \quad \beta = [1 - (v/c)^2]^{-1/2}$$

and in the same coordinates the difference in energy of the two states, which gives the line displacement, will be

$$E(\beta - 1)$$

But this can only be finite if E is finite which, by (31), it is not.

We have treated these difficulties in some detail, because they show that the present theory will not be applicable to any problem where relativistic effects are important, where, that is, we cannot be guided throughout by the limiting case $c \rightarrow \infty$. The theory can thus not be applied to a discussion of the structure of the nuclei. It appears improbable that the difficulties discussed in this work will be soluble without an adequate theory of the masses of electron and proton; nor is it certain that such a theory will be possible on the basis of the special theory of relativity.

THE EFFECT OF END LOSSES ON THE CHARACTERISTICS OF FILAMENTS OF TUNGSTEN AND OTHER MATERIALS

BY IRVING LANGMUIR, SAUNDERS MACLANE AND KATHARINE B. BLODGETT
GENERAL ELECTRIC COMPANY, SCHENECTADY, NEW YORK

(Received September 20, 1929)

ABSTRACT

The leads of a tungsten filament in vacuum cool the ends of the filament and so affect the voltage, candle power, electron emission and other properties of the filament. For long filaments, where there is a central portion at a uniform temperature T_m , the temperature distribution near the lead is derived. A method for determining T_0 , the temperature of the lead-filament junction, is given. Tables and formulas are presented which allow ready calculation of the effect of the leads on the properties of any long tungsten filament for which the current and diameter are known. From the more general results it has been found that the decrease in voltage due to the cooling of one lead may be represented by $\Delta V = 0.154 (T_m/1000) - 0.081 (T_0/1000) - 2.1 \cdot 10^{-3} T_0 T_m - 0.056$. There is an extension of the theory to cover the cases of filaments in gases, filaments of other materials, etc.

Part II of the paper gives figures from which may be found the properties of filaments so short that the first theory does not apply. Some experimental checks of the theory are given.

In general the results and the methods of application have been placed first, and the mathematical derivations have been placed at the end of each part.

For a short filament with leads cooled in liquid air a negative slope of the volt-ampere characteristic when the central temperature is much smaller than T_m is observed.

PART I. THE LONG FILAMENT

THE extensive use of tungsten filaments in research and industry makes it important to consider how the cooling effects of the leads influence the characteristics of such filaments. For wide ranges of temperature the characteristics of hypothetical filaments which are not cooled by leads may be found from tables of the properties of tungsten¹⁻⁷. The magnitudes of the lead losses have been evaluated experimentally^{1, 8, 9} and by theoretical methods.¹⁰ It is felt that there is still a place for a systematic treatment

which may be conveniently applied to a filament operated under any ordinary conditions.¹¹

Temperature distribution. For most tungsten filaments the cooling effect of the leads does not extend appreciably to the central portion of the filament. The absolute temperature, T_m , of this portion may be calculated from the diameter of the filament and the current through it.¹² The temperature of other parts of the filament is best expressed as a fraction, θ , of T_m . Thus $\theta = T/T_m$, where T represents the absolute temperature of any point of the filament.

We may consider the effect of each lead independently, since the two effects do not overlap. Of fundamental importance is the variation of θ with x , the distance from the lead. This is shown later to be governed by the equation,

$$\phi = ad\theta/dx \quad (1)$$

where ϕ is a function of θ , and is given by Eq. (30). a is a parameter of the dimension of length, and depends on T_m and the filament diameter D .

TABLE I. Values of a_0 for various values of T_m . (For ' a ' use Eq. (2).)

The temperature distribution near a cooling lead is represented by the curve farthest to the right (labeled 0.995) in Fig. 2 (Part II). The increment in the abscissa $(x/a)_0^\theta$ from the ordinate θ_2 to ordinate θ_1 gives the distance along the filament from a point at temperature $\theta_1 T_m$ to a point at temperature $\theta_2 T_m$.

In practice the junction of lead and filament will be at a temperature $T_0 = \theta_0 T_m$. The exact determination of this temperature is rather difficult. If the leads are short and fairly heavy we may assume $T_0 = T_R$, where T_R is the room temperature. The error due to this assumption in the value of any filament-property for the whole filament¹³ computed by the methods of this paper will be less than 1 percent when the length of the lead is less than a certain maximum length l_0 . We find that l_0 is given approximately by

$$l_0 = 0.32(x/a)(D_L/0.1)^2(\lambda_L/0.586)/A. \quad (4a)$$

A is the filament current in amperes and (x/a) represents the half length of the filament. D_L is the lead diameter in cm. λ_L is the thermal conductivity of the lead in watts $\text{cm}^{-1} \text{deg}^{-1}$. For nickel leads $\lambda_L/0.586 = 1$, for tungsten leads $\lambda_L/0.586 = 2.73$, for molybdenum $\lambda_L/0.586 = 2.49$.

Thus with nickel leads for which $D_L = 0.1$ cm and $l < 1.6$ cm, used with a 20 cm filament of $D = 0.02$ cm for which the highest operating temperature is $T_m = 2400^\circ$ we may assume $T_0 = T_R$, since we find $A = 4.02$,¹² $x/a = 20.2$, and thence from Eq. (4a) $l_0 = 1.6$ cm.

For leads such as those used in incandescent lamps it is sufficiently accurate for many purposes to assume that $T_0 = (1/4)T_m$.

If desired we may evaluate $\Delta T = T_0 - T_R$ in terms of the lead length l . We find that

$$\Delta T = l \cdot A (0.586/\lambda_L)(0.1/D_L)^2 (\Delta T_0). \quad (4b)$$

$(\Delta T)_0$ is the value of ΔT for a nickel lead for which $D_L = 0.1$ cm, $l = 1$ cm and $A = 1$ amp. It is given in Table III as a function of the value of T_m for the filament. Note that these values are for a filament of constant current,

¹³ Such as the voltage or the candle power of the whole filament.

and hence that the diameter of a filament for which $\Delta T = (\Delta T)_0$ is smaller for the higher temperatures in the table.

The data from Table III are not dependable above $T_0 = 1000^\circ$, where radiation loss is appreciable, nor when the resistance loss in the lead is large.

TABLE III. $(\Delta T)_0 = T_0 - T_R$ for nickel leads when $A=1$, $D_L=0.1$, $l=1$.

$T_m(^{\circ}\text{K})$	$(\Delta T)_0$	T_m	$(\Delta T)_0$	T_m	$(\Delta T)_0$
1000°	21°	1800°	45°	2800°	80°
1200	26	2000	51	3000	87
1400	32	2200	58	3200	95
1600	38	2400	65	3400	102
		2600	72		

The actual temperature distribution of the filament is given by (cf. Eq. (3))

$$(x/a)_{\theta_0}^{\theta} = \int_0^{\theta} d\theta/\phi - \int_0^{\theta_0} d\theta/\phi. \quad (5)$$

To find the distance from the lead, x , of a point of known temperature θ , we may evaluate the two integrals above by means of Table II, and then obtain x from $(x/a)_{\theta_0}^{\theta}$ by using Table I. Conversely we may find the temperature θ of a point at any given distance, x .

By the use of data on the characteristics of tungsten filaments as functions of temperature,^{1, 3} and from the temperature distribution along a filament as found above, the properties of the filament at each point can be calculated. For example, we can determine the electron emission, the radiated energy, the luminous intensity, et cetera, at each point.

The effect of lead losses on filament characteristics. Many filament properties which are functions of the temperature would be strictly proportional to the length of the filament if the temperature were everywhere uniform. Let h be a quantity which measures some one of these properties *per unit length* at any given absolute temperature T . For example, h may represent the voltage drop per cm or the electron emission per cm of length. Let h_m be the value of h at the temperature T_m . Nearly all the properties of tungsten which we shall need to consider vary in proportion to some definite power of the temperature over rather wide ranges. Thus we may put

$$h = h_m \theta^n \quad (6)$$

$$n = (dh/h)(T/dT) \quad (7)$$

where n is approximately constant.¹⁴

If a filament of length $2x$ were all at its maximum temperature T_m the value H_m of any property for the whole filament would be

$$H_m = 2xh_m. \quad (8)$$

¹⁴ For values see Ref. 3, p. 354 Table II or Ref. 1, p. 153 Table I-B.

The cooling effect of the leads makes H , the actual value of the property for the whole filament, less than H_m . ΔH , the amount of this decrease due to one lead, may be thought of as the total value of the property over a short length of uncooled filament. Designate by ΔV_H the voltage drop across this length. ΔV_H is then the volt-equivalent of ΔH , and the fractional decrease of H_m can thus be expressed as a fraction of the total voltage V_m

$$\Delta V_H/V_m = \Delta H/H_m. \quad (9)$$

The ratio H/H_m is a measure of the extent to which the cooling effect changes the property. We have

$$H/H_m = (H_m - 2\Delta H)/H_m = (V_m - 2\Delta V_H)/V_m. \quad (10)$$

The factor 2 accounts for two leads.

TABLE IV. Values of $B_1 = \int_0^1 (1 - \theta^n) d\theta / \phi$.

n	B_1	n	B_1	n	B_1
1	0.583	9.0	1.626	20	2.032
1.2	0.660	10	1.682	22	2.079
2.0	0.882	11	1.728	24	2.124
3.0	1.076	12	1.772	25	2.145
4.0	1.217	13	1.813	26	2.165
5.0	1.329	14	1.850	28	2.203
5.1	1.339	15	1.885	30	2.238
6.0	1.421	16	1.918	35	2.315
7.0	1.500	17	1.949	40	2.384
8.0	1.566	18	1.978	50	2.497
		19	2.006	60	2.589

If V is the actual voltage drop (in volts) and ΔV the value which ΔH has when the property measured by H is voltage

$$H/H_m = (V + 2\Delta V - 2\Delta V_H)/(V + 2\Delta V). \quad (11)$$

It will be shown later that the value of ΔV_H is given by

$$\Delta V_H = 1.812 \cdot 10^{-5} T_m^{1.3} [B_1 - \beta(\theta_0)]. \quad (12)$$

B_1 is given in Table IV. It is a function of n , the temperature exponent for the property H in question. For $n > 5$, B_1 is given by the equation

$$B_1 = 0.5170 + 1.1660 \log_{10} n - 0.0591/n + 0.2224/n^2 + 0.0140/n^3 - 0.468/n^4 + \dots \quad (13)$$

The coefficient of Eq. (12), $1.812 \cdot 10^{-5} T_m^{1.3}$, is given in Table V.

$\beta(\theta_0)$ in Eq. (12) is a function of θ_0 . It is independent of n if $n > 4$ and $\theta_0 < 0.5$, and is given by

$$n > 4, \theta_0 < 0.5 \quad \beta(\theta_0) = (x/a)_{\theta_0}^{\theta_0}. \quad (14)$$

This value of x/a is to be taken directly from Table II for $\theta = \theta_0$. For $n = 1.2$ (the exponent for resistance and the only important small value of n) $\beta(\theta_0)$ is given in the third column of Table II.

TABLE V. $1.812 \cdot 10^{-5} T_m^{1.3}$

T_m	$1.812 \cdot 10^{-5} T_m^{1.3}$	T_m	$1.812 \cdot 10^{-5} T_m^{1.3}$
1000°	0.1439	2300°	0.4250
1100	.1629	2400	.4493
1200	.1825	2500	.4737
1300	.2024	2600	.4985
1400	.2229	2700	.5236
1500	.2438	2800	.5490
1600	.2651	2900	.5744
1700	.2869	3000	.6003
1800	.3091	3100	.6266
1900	.3316	3200	.6528
2000	.3544	3300	.6797
2100	.3777	3400	.7066
2200	.4011	3500	.7337

Since the current is constant, the voltage has the same temperature exponent as the resistance. Hence ΔV may be found from Eq. (12) by setting $n = 1.2$. In many cases to apply Eq. (11) it may be easier to find the theoretical voltage $V_m = V + 2\Delta V$ directly from the resistivity at T_m and the filament dimensions. The wattage *input* depends on the resistance of the filament and hence ΔV_H in this case is to be found for $n = 1.2$. The wattage *radiated* on the other hand depends on $n = 5.1$ or thereabouts.¹⁵

Method of application. In finding the value of B_1 for Eq. (12) from the value of n , we notice that for most properties of tungsten n is not constant as was assumed, but varies slightly with the temperature. We must take a mean value of n , that is, its value at some effective temperature T_E . This temperature is roughly that at which $h = h_m/2$. This temperature and the corresponding value of n may be found directly.¹⁴

As an alternate method to find T_E we note that for some properties h may be quite accurately expressed as

$$h = CT^k e^{-b/T}. \quad (15)$$

Thus for candle power Wiens' law (using a Crova wave-length) gives $k = 0$, $b = 25200^\circ$. The Richardson-Dushman equation for the electron emission from pure tungsten has $k = 2$, $b = 52600^\circ$. The rate of evaporation of a tungsten filament is expressed by Eq. (15) with $k = 0$, $b = 94100^\circ$. Setting $h = h_m/2$ in Eq. (15) and using Eq. (6) to evaluate the term in k , we find approximately

$$b/T_E = b/T_m + [1 - k/n] \log_e 2. \quad (16)$$

Differentiating Eq. (15) and comparing with Eq. (7) we see that

$$n = k + b/T. \quad (17)$$

Hence from Eq. (16) and the values of the constants given above we obtain the following equations for effective values of n in terms of T_m

$$\text{candle power } n = 25200^\circ/T_m + 0.7 \quad (18)$$

¹⁵ Ref. 3, p. 312, Table I, column 5.

$$\text{electron emission } n = 52600^\circ/T_m + 2.6 \quad (19)$$

$$\text{evaporation } n = 94100^\circ/T_m + 0.7. \quad (20)$$

The decrease in the rate of evaporation near the leads is ordinarily not a matter of experimental interest, but under certain conditions its effects may be directly observed. Nitrogen or carbon monoxide in the presence of a tungsten filament at very high temperatures gradually disappears because every atom of tungsten which evaporates combines with a molecule of the gas to form a stable and non-volatile compound. Thus the rate of "clean-up" of the gas depends on the total amount of metal that evaporates.

The direct application of Eq. (12) as outlined above is the most accurate method for the evaluation of ΔV_H . In many cases where only approximate results are desired ΔV_H may be found from the following empirical equations, which were found to fit the data calculated from Eq. (12). The deviation from the results of Eq. (12) is less than the amount tabulated for the given range. The actual error of the results may in some cases be larger than this, due to approximations in the derivation of Eq. (12).

TABLE VI. $\Delta V_H = P(T_m/1000) - Q(T_0/1000) - R$ volts.

<i>H</i> is	<i>P</i>	<i>Q</i>	<i>R</i>	Range— <i>T_m</i>	Range— <i>T₀</i>	Range— <i>θ₀</i>	Max. error (volts)
Voltage*	0.154*	0.081*	0.056*	1000–2500°	any values	0.1–0.5	0.004
Candle Power	.338	.182	–.004	600–3500	300–1400°	.1–.5	.01
Electron emission	.440	.158	.072	1000–3500	300–900	.07–.5	.009
Evaporation	.480	.160	.060	1500–3500	300–900	.07–.5	.008
Watts radiated	.293	.160	.084	1100–3000	300–900	.1–.4	.01

* For voltage (Watts input) a term $-2.1 \cdot 10^{-8} T_0 T_m$ is to be added to the right hand side of Eq. (21).

In many cases with short, heavy leads $T_0 = 300^\circ$. In these circumstances the following approximate equations hold.

TABLE VII. $\Delta V_H = P_0(T_m/1000) - S$ volts (22)

<i>H</i> is	<i>P₀</i>	<i>S</i>	Range— <i>T_m</i>	Max. error (volts)

Computation of T_m . If we know the diameter of a filament and the current through it, T_m may be obtained directly from Tables which give temperature tabulated against current divided by $d^{3/2}$.¹²

If the diameter is not known, but if the length $2x$ is known, the voltage V and amperage A corresponding to the temperature we wish may be found. Assuming that the filament is all at the maximum temperature T_m , we compute $VA^{1/3}/(2x)$ and find a first approximation for T_m .¹⁶ For

¹⁶ Ref. 3, p. 312, Table I, column 6 gives $VA^{1/3}/(2x)$ as a function of T .

this value of T_m there is a certain voltage correction ΔV . This gives us a much better value, $V+2\Delta V$, for the voltage if the filament were all at T_m . $(V+2\Delta V) A^{1/3}/(2x)$ then gives us a second approximation for T_m . As many approximations as desired may be made.

Shorter filaments. With shorter filaments the cooling effects of the two leads overlap, and the temperature at any point may be found approximately by adding the cooling effect of each lead at that point. With still shorter filaments these temperatures and the values of H/H_m found as above are in error. The amount of the error depends on n , the temperature exponent of the property in question. Part II, Table X gives in column 2 the maximum value of the half length $(x/a)_{0\%}^0$ for which the error in H/H_m is less than 1 percent. Column 3 gives similar information for 5 percent error. For details see Part II.

DERIVATION OF THE EQUATIONS

The fundamental differential equation giving the temperature distribution near a cooling lead is⁸

$$A^2 r + [\lambda(d^2 T/dx^2) + (d\lambda/dT)(dT/dx)^2] \pi D^2/4 = w. \quad (23)$$

The symbolism is explained in Table VIII. The terms $A^2 r$ and w correspond respectively to the rate of production of energy and the rate of radiation

TABLE VIII. *Symbols.*

A	Filament current in amps	w	$=h$ for power radiated
D	Filament diameter (cm)	r	$=h$ for resistance
D_L	Lead diameter (cm)	v	$=h$ for voltage drop
l	Length of lead (cm)	H	Value of any property for the whole filament
x	Distance along filament (cm)	H_m	Value of H if the whole filament were at T_m
a	Unit of length (cm) Table I	V	$=H$ for voltage drop
a_0	a for $D=0.01$ cm	H_c	Value of H if the whole filament were at T_c
sub m	Value at the uncooled central portion of the filament	n	Temperature exponent for any property $=d \log h/d \log T$
sub c	Value at the center of the filament (Part II)	ρ	$=n$ for resistance
T	Absolute temperature	ω	$=n$ for radiation
T_R	Room temperature	k	$=n$ for thermal conductivity
$T_0 = \theta_0 T_m$	Lead-filament junction temperature	ϕ	$=ad\theta/dx$
ΔT	$=T_0 - T_R$	ΔV_H	see Eq. (12)
θ	$=T/T_m$	B_1	Table IV
$(x/a)_{\theta_1}^{\theta_2}$	Distance in a -units from point at θ_1 to point at θ_2	B_{15}	Value of B_1 for $\omega=5$
λ	Thermal conductivity of filament	$\beta(\theta_0)$	Table II
λ_L	Thermal conductivity of lead	τ_0	$=T_0/T_c$
h	Value of any property per cm of filament length		

of energy per unit length of filament, while the expression involving λ corresponds to the net rate of conduction of energy into an element of the filament.

An inspection of tables giving the characteristics of tungsten filaments as functions of the temperature shows that it is possible to express Eq. (23) in a much simpler form.³

The resistance of a tungsten filament can be expressed quite accurately over a wide range of temperatures by the equation $r = cT^\rho$, where c is a constant and $\rho = 1.20$ (for the range between 600°–3,000°K). Similarly the radiated power may be expressed approximately by the relation $w = c'T^\omega$, where ω is fairly constant, having the values, 5.65 at 1,000°K, 5.12 at 1700°, 4.93 at 2,000°, 4.71 at 2,400° and 4.48 at 3,000°. In the majority of experiments in which it is desired to calculate the cooling effect of the leads the temperature of the hottest part of the filament will probably be below 2,400°. By averaging the values of this exponent from 2,000° to 400°, weighing each in proportion to the corresponding value of w , the effective exponent is found to be 5.1. We shall, therefore, take this to be the value of ω . Even at very high filament temperatures, where the effective exponent would be about 4.7, we shall see that the error made by using $\omega = 5.1$ is practically negligible.

The heat conductivity of tungsten at temperatures from 1,300 to 2,500° has been given by Forsythe and Worthing.¹ It ranges from 0.93 watts $\text{cm}^{-1} \text{deg}^{-1}$ at 1,300° to 1.21 at 2,500°. We find that the empirical equation

$$\lambda = 0.840(T/1000)^{0.4} \quad (24)$$

expresses the values of λ at the 13 observed points given in their table (at 100° intervals) within an error of 0.0022 or about 0.2 percent.

This equation is used throughout this paper.

In the central uncooled portion w_m , the power radiated per unit length, is equal to $A^2 r_m$, where r_m is the resistance per unit length at this place. Since A is constant throughout the length of the filament, the temperature exponent of $A^2 r$ is the same as that of r , that is ρ . Hence we can replace the first term in Eq. (23) by $w_m \theta^\rho$. Similarly w may be replaced by $w_m \theta^\omega$. From Eq. (24) we obtain the relation $\lambda = \lambda_m \theta^{0.4}$, where λ_m is the thermal conductivity at temperature T_m . Using the values of λ and $d\lambda/dT$ from this relation, we obtain from Eq. (23)

$$d^2\theta/dx^2 + 0.4(d\theta/dx)^2/\theta = (\theta^{\omega-0.4} - \theta^{\rho-0.4})/a^2 \quad (25)$$

where a is a parameter defined by

$$a^2 = \pi D^2 \lambda_m T_m / 4 w_m. \quad (26)$$

We can replace w_m by its value v_m^2/r_m where v_m is the voltage drop per cm at temperature T_m . The factor $r_m D^2$ which then occurs in the equation is independent of D and varies as $T_m^{1.2}$ (it is in fact the function R' given by Jones and Langmuir).³ Thus

$$r_m D^2 = 7.89 \cdot 10^{-9} T_m^{1.2}. \quad (27)$$

From Eqs. (24), (26), (27)

$$a = 1.812 \cdot 10^{-5} T_m^{1.3} / v_m. \quad (28)$$

In computing a from this equation v_m was found from Tables of characteristics.¹³ Since $v_m \propto D^{-1/2}$, we obtain Eq. (2).

In Eq. (25) set $\omega=5.1$, $\rho=1.2$ and substitute ϕ as defined by Eq. (1) for x

$$\phi d\phi/d\theta + 0.4\phi^2/\theta = \theta^{4.7} - \theta^{0.8}. \quad (29)$$

By taking as new variables ϕ^2 and $\log \theta$ this equation becomes linear and may be solved in the usual way to give

$$\phi^2 = (3 - 5\theta^{2.6} + 2\theta^{6.5})/6.5\theta^{0.8}. \quad (30)$$

The constant of integration, 3, is fixed by the condition that $d\theta/dx=0$, and therefore $\phi=0$ at $\theta=1$, the center of the filament.

For values of θ close to unity (30) may be expanded in terms of $Z=1-\theta$

$$\phi^2 = 3.9Z^2 - 4.81Z^3 + 3.715Z^4 - 0.8886Z^5 + 0.4068Z^6 + 0.27Z^7 + \dots \quad (31)$$

Temperature distribution. When $\theta \leq 0.6$ the integral in Eq. (2) may be found by expanding $1/\phi$ in the series

$$1/\phi = 1.472\theta^{0.4} [1 + (5/6)\theta^{2.6} + (25/24)\theta^{5.2} - (1/3)\theta^{6.5} + 1.447\theta^{7.8} - (5/6)\theta^{9.1} + \dots]. \quad (32)$$

Integration gives

$$(x/a)_0^\theta = 1.0514\theta^{1.4} + 0.3067\theta^4 + 0.2323\theta^{6.6} - 0.0621\theta^{7.9} + 0.231\theta^{9.2} - 0.117\theta^{10.5} + \dots \quad (33)$$

When $\theta \geq 0.6$ Eq. (31) gives

$$1/\phi = 0.5064 [1 + 0.6167Z + 0.0941Z^2 - 0.1809Z^3 - 0.227Z^4 - 0.172Z^5 + \dots] / Z. \quad (34)$$

Integrating we obtain the indefinite integral, and find the integration constant by comparison with Eq. (33) at $\theta=0.6$, where both series are sufficiently convergent to give results accurate to 1 part in 1,000

$$(x/a)_0^{1-Z} = 0.2247 - 1.1660 \log_{10} Z - 0.3123Z - 0.0238Z^2 + 0.0305Z^3 + 0.0287Z^4 + 0.0174Z^5 + \dots \quad (35)$$

Column 2, Table II was calculated from Eqs. (33) and (35).

Lead-filament junction temperature. The rate of flow of heat, Q , in watts, past any point of the filament is equal to the integral, from that part to the center, of the difference between the heat generated by resistance and that lost by radiation.

$$Q = w_m a \int_{\theta}^1 (\theta^{1.2} - \theta^{5.1}) d\theta / \phi. \quad (36)$$

Setting $w_m = Av_m$, substituting for a from Eq. (28), and integrating

$$Q = (1.812 \cdot 10^{-5} T_m^{1.3}) 6.5^{-0.5} (3 - 5\theta^{2.6} + 2\theta^{6.5})^{0.5} A \quad (37)$$

where θ corresponds to the temperature of the point in question.

For short fairly heavy leads at temperatures below 1,000°K the resistance loss and radiation loss in the lead are negligible. All the heat that flows into the lead from the filament must flow out at the cold end, which may be assumed to be at room temperature. Taking the heat conductivity of nickel leads as constant at 0.586 watts cm⁻¹ deg⁻¹, the leads have a constant temperature gradient given by

$$\lambda_L(dT/dl)\pi D_L^2/4=Q. \quad (38)$$

Consequently for the total temperature difference $\Delta T = T_0 - T_R$ for the leads we obtain

$$\Delta T = 4lQ/(\pi D_L^2 \lambda_L). \quad (39)$$

Eqs. (37) and (39) give Eq. (4b) for ΔT in terms of $(\Delta T)_0$. To find the latter we notice that the lead temperature θ_0 has little effect on Q . Setting $\theta_0 = 0.24$, $A = 1$, $l = 1$, $D_L = 0.1$, $\lambda_L = 0.586$, we obtain from Eqs. (37) and (39)

$$(\Delta T)_0 = 145 [1.812 \cdot 10^{-5} T_m^{1.3}]. \quad (40)$$

Eq. (40) was used in conjunction with Table V to compute Table III.

Filament characteristics. We have

$$2\Delta H = H_m - H = 2a \int_{\theta_0}^1 (h_m - h) d\theta/\phi. \quad (41)$$

Applying Eqs. (6) and (28) and substituting for h_m/v_m the equal ratio H_m/V_m , where V_m is the voltage drop that would exist between the ends of the filament if it were all at the temperature T_m

$$\Delta V_H = \Delta H(V_m/H_m) = 1.812 \cdot 10^{-5} T_m^{1.3} \int_{\theta_0}^1 (1 - \theta^n) d\theta/\phi. \quad (42)$$

ΔV_H is a convenient symbol for the expression $\Delta H(V_m/H_m)$. It represents the voltage across a section of uncooled filament of such length that H_m for this section would equal the decrease caused by the cooling effect of the lead. The advantage of this nomenclature is that it requires no knowledge of filament diameter or length.

By breaking up the integral of Eq. (42) into

$$B_1 = \int_0^1 (1 - \theta^n) d\theta/\phi \quad (43)$$

and

$$\beta(\theta_0) = \int_0^{\theta_0} (1 - \theta^n) d\theta/\phi \quad (44)$$

we obtain Eq. (12).

In evaluating B_1 , we meet the difficulty that we must use two different series for $1/\phi$, one for small and the other for large values of θ . Let $1/\phi_1$

be the value of $1/\phi$ given by the first six terms only of the series in Eq. (32) and $1/\phi_2$ by the first six terms only of the series in Eq. (34). We have

$$\begin{aligned} 0 &\leq \theta \leq 0.5 & \phi &= \phi_1 \\ 0.5 &< \theta < 0.65 & \phi_1 &= \phi = \phi_2 \\ 0.65 &\leq \theta \leq 1 & \phi &= \phi_2. \end{aligned}$$

Since the series are equivalent between 0.5 and 0.65 we may put

$$B_1 = \int_0^t (1-\theta^n) d\theta / \phi_1 + \int_t^1 (1-\theta^n) d\theta / \phi_2$$

where $0.5 < t < 0.65$. A simple transformation gives

$$B_1 = \int_0^t (1-\theta^n) (1/\phi_1 - 1/\phi_2) d\theta + \int_0^1 (1-\theta^n) d\theta / \phi_2. \quad (45)$$

The value of $1/\phi_1 - 1/\phi_2$ is practically zero for values of θ between 0.5 and 0.65, and therefore the value of the first integral is not dependent on the actual value of t . Even at $\theta = 0.1$ the value of $1/\phi_1 - 1/\phi_2$ is only 0.117, but at $\theta = 0$ it becomes 0.573. Thus the larger part of the first integral is for values of $\theta < 0.1$. In this range θ^n may be neglected in comparison with unity for all large values of n . Even if $n = 1$ the error in neglecting θ^n will be small.

Calling the first integral of Eq. (45) F_1 , we have

$$\begin{aligned} F_1 &= \int_0^t d\theta / \phi_1 - \int_0^t d\theta / \phi_2 \\ &= (x/a)_0^t - \int_0^t d\theta / \phi_2. \end{aligned} \quad (46)$$

Designate the right hand side of Eq. (35) by F_2 . From the derivation of this equation

$$F_2 + C = \int d\theta / \phi_2$$

C being a constant of integration. Hence

$$\int_0^t d\theta / \phi_2 = [F_2 + C]_{\theta=0}^{\theta=t} = [F_2 + C]_{z=1}^{z=1-t} = F_2(1-t) - F_2(1).$$

But from Eq. (35) $F_2(1-t) = (x/a)_0^t$. Hence from Eq. (46)

$$F_1 = F_2(1) = -0.0348$$

the numerical value being found by setting $z = 1$ in the expression for F_2 in Eq. (35). Due to the definition of ϕ_2 this value is not affected by the missing terms of the series.

Putting the value of $1/\phi_2$ from Eq. (34) in the second integral of Eq. (45), we find

$$B_1 = -0.0348 + 0.5064 \sum_{p=1}^6 A_p \int_0^1 (1-\theta^n)(1-\theta)^{p-2} d\theta$$

where A_1, A_2, A_3 are the coefficients, 1, 0.6167, etc., in the series in Eq. (34). This reduces to

$$B_1 = 0.2247 + 0.5064 \int_0^1 (1-\theta^n) d\theta / (1-\theta) - 0.3123 / (n+1) \\ - 0.0477 [(n+1)(n+2)]^{-1} + 0.1833 [(n+1) \cdots (n+3)]^{-1} \cdots \quad (47)$$

the coefficients of the next two terms being 0.6894 and 2.092.

If n is an integer we have

$$\int_0^1 (1-\theta^n) d\theta / (1-\theta) = 1 + \frac{1}{2} + \frac{1}{3} + \frac{1}{4} + \cdots + 1/n \quad (48)$$

and for other values of n the integral can be expressed in terms of gamma functions. For $n=1.2$, its value is 1.1216. For large values of n the integral is given by the series

$$\int_0^1 (1-\theta^n) d\theta / (1-\theta) = 0.5772 + \log_e n + 1/2n \\ - [12n(n+1)]^{-1} - [12n(n+1)(n+2)]^{-1}. \quad (49)$$

Inserting this value in Eq. (47) and expressing as a series in reciprocal powers of n we obtain Eq. (13).

In computing Table IV for values of n less than 5, Eq. (47) was used but Eq. (13) was found more convenient for the larger values.

To evaluate $\beta(\theta_0)$ we note that in general $\theta_0 < 0.5$ and hence that for fairly large n the term θ^n is negligible, and Eq. (14) holds. For ΔV , when $n=1.2$, $\beta(\theta_0)$ for the third column of Table II was obtained by using the series expansions of $1/\phi$ given by Eqs. (32) and (34).

Application under other conditions. For filaments in the presence of gas, or for filaments of materials other than tungsten there will be changes in the values used in Eq. (29) for ω , ρ and k , where k is the temperature exponent of the thermal conductivity. By methods similar to the derivation of Eq. (30) we find that the general expression for ϕ is

$$\phi^2 = 2\theta^{-2k} [(1-\theta^{\rho+k+1})/(\rho+k+1) - (1-\theta^{\omega+k+1})/(\omega+k+1)]. \quad (30a)$$

The integral B_1 in Eq. (12) may be found by numerical integration or by direct integration in some cases. Thus, when $\omega+k+1=2(\rho+k+1)$, ϕ^2 is a perfect square, and

$$B_1 = (\omega-\rho)^{-1/2} \{ \psi[(n+k+1)/(\rho+k+1)] - \psi[(k+1)/(\rho+k+1)] \} \quad (50)$$

where $\psi(x) = d \ln \Gamma x / dx$ is the logarithmic derivative of the gamma function. Table IVa gives some values of B_1 obtained in some of these ways.

TABLE IVa.
 $B_1 = \int_0^1 (1 - \theta^n) d\theta / \phi$ for various exponents ω, ρ, k, n

ω	ρ	k	n	B_1
5.1	0.0	1.0	5.1	1.695
4.3	1.85	-.4	20.	4.079
6.0	1.0	1.0	1.0	0.371
4.0	1.0	1.0	1.0	0.428
4.0	1.0	1.0	5.0	1.118
4.0	1.0	1.0	10.0	1.486
4.0	1.0	1.0	20.0	1.871
4.0	1.0	1.0	40.0	2.264
3.8	1.2	0.4	27.2	2.522

Data such as those in Table IVa show that the variation of B_1 with ω is small and may be represented thus

$$\text{For } n = \rho \quad B_1 = B_{15} [1 + 0.077(5.0 - \omega)] \quad (51a)$$

$$\text{For } n = 20 \quad B_1 = B_{15} [1 + 0.100(5.0 - \omega)] \quad (51b)$$

where B_{15} is the value of B_1 for $\omega = 5.0$. B_{15} may be found by these equations from tables of B_1 such as Table IVa. Fig. 1 is a plot of B_{15} as abscissa against ρ as ordinate for constant values of k . The full lines are for voltage correction, $n = \rho$. The dotted lines are for $n = 20$.

Fig. 1. Plot of B_{15} ($\omega = 5$) against ρ for constant k .
 Full lines $n = \rho$. Dotted lines $n = 20$.

The deviations of B_1 found from Fig. 1 from the value of B_1 , for the same n , found in Table IV may be expressed as a fraction, N , of the latter value. The variation of N with n , for constant values of ω, ρ and k may be approximately expressed by

$$N(n) = N(20) - \alpha(20 - n) [N(20) - N(\rho)] / (20 - \rho) \quad (51c)$$

where

n	ρ	5	10	30	40
α	1	0.42	0.27	0.15	0.11

We may find B_1 for any exponents n , ω , k and ρ by finding $N(20)$ and $N(\rho)$ for the appropriate values of ω , k and ρ from Fig. 1 and Eqs. (51a) and (51b). Eq. (51c) and Table IV then give the desired B_1 .

Other metals. From Eq. (26) and the derivation of Eq. (28) we see that

$$a = (\lambda_m T_m R_m / v_m)^{1/2} \quad (28a)$$

where R_m is the resistivity of the metal in question at the temperature T_m . We then have

$$\Delta V_H = (\lambda_m T_m R_m)^{1/2} [B_1 - \beta(\theta_0)]. \quad (12a)$$

The Wiedemann-Franz law states that, at a given temperature, λR , and hence the coefficient in Eq. (12a), is approximately the same for most metals and alloys. This coefficient is thus given by $1.812 \cdot 10^{-5} T_m^{1.3}$ in Table V. Consequently the magnitude of ΔV_H may be found for any metal which obeys this law with the help of Fig. 1 and the assumption that the change of $\beta(\theta_0)$ is similar to that of B_1 .

End losses from filaments in the presence of gas. Gas around a filament causes a loss of heat by conduction and increases the voltage required to reach a given T_m . Eq (12a) shows that for a fixed T_m , ΔV_H is the same for filaments in gas and vacuum except for the variation in the values of B_1 and $\beta(\theta_0)$. The latter may be evaluated by considering the conduction loss to be part of the radiation loss w in Eq. (23). Thus if at T_m the conduction loss is $1/4$ of the radiation loss, and if the conduction loss varies as $T^{1.7}$,¹⁷ the effect on B_1 may be represented as a change in the effective value of ω from 4.6 to 3.8, which by Table IVa means an increase of about 15 percent in the values of B_1 given in Table IV. In general the values of ΔV_H for vacuum hold with fair accuracy for small gas pressures, but the temperature distribution is altered.

For new filament materials or other new conditions there will be no accurate knowledge of the filament characteristics and the temperature exponents for the application of the above method, which method nevertheless will, we hope, still be capable of indicating whether or not lead losses are important in any given case.

PART II. LEAD LOSSES IN SHORT FILAMENTS

Temperature distribution. Shorter filaments do not admit the assumption, made for most of the results of Part I, that the central portion of the filament is not cooled by the leads. Even the calculation of temperature distribution by adding the effects of the two leads is not very good in these cases. Thus when x/a , the filament half length, is 1.53, for which the cooling effect of one lead at the other gives $\theta = 0.994$, the long filament case gives a central temperature corresponding to $\theta = 0.85$, while the true value is $\theta = 0.8$. Theoretically the maximum temperature T_m can only be attained in an infinitely

¹⁷ These conditions are approximately those for a filament of 0.007 cm diameter at $T_m = 2900^\circ$ in 10 mm of N_2 . See I. Langmuir and G. M. J. Mackay, J. Amer. Chem. Soc. 36, 1717 (1914). For larger filaments the conduction losses are relatively smaller.

long filament (cf. Eq. (35)). A "short filament" is one for which this fact invalidates the conclusions of Part I.

Let T_c be the actual temperature at the center of the filament, and let the larger value T_m still indicate the temperature of a hypothetical portion uncooled by leads as calculated from the current and diameter of the filament. Let $\theta_c = T_c/T_m$.

Eq. (1) holds as before with a more complicated value for ϕ . If $(x/a)_{\theta_0}^{\theta_c}$ is the distance from the center to a lead at temperature $T_0 = \theta_0 T_m$, we have, as before

$$(x/a)_{\theta_0}^{\theta_c} = \int_{\theta_0}^{\theta_c} d\theta/\phi \quad (52)$$

a has the same values as before, and is given in Table I.

Table IX gives the values of $(x/a)_{\theta_0}^{\theta_c}$ for various values of θ_c . Fig. 2 gives the plot of $(x/a)_{\theta_0}^{\theta_c}$ as abscissa against θ as ordinate, for constant values of θ_c . The value of θ_c for any curve is of course the intercept on the θ axis.

Fig. 2. Plot of $(x/a)_{\theta_0}^{\theta_c}$ against θ for constant values of θ_c .

These curves are temperature distribution curves. Thus if $\theta_c = 0.8$ the curve with that intercept gives us the temperature (θ) at any distance, $(x/a)_{\theta_0}^{\theta_c}$, from the center. To find for any filament the value of θ_c , we need know only one point on the temperature distribution curve. Thus for a filament of known length and of known lead temperature, a point having the coordinates $(x/a)_{\theta_0}^{\theta_c}$, θ_0 is determined on the plot. This point lies on some temperature distribution (constant θ_c) curve—probably not one of these drawn. The value of θ_c may readily be found, however, by interpolating between the two nearest curves. By continuing this interpolation down to the x/a scale, the value $(x/a)_{\theta_0}^{\theta_c}$ is found. This is the value that would obtain if the given

filament were prolonged until its leads were at 0°K, and were left otherwise unchanged. If desired, $(x/a)_{\theta_c}^{\theta_0}$ may be found from θ_c by interpolating in Table IX.

Of course the value of any property h at any point of the filament may be found by first finding the temperature at that point, then applying published data on filament characteristics.^{1,3}

TABLE IX. Relation between the temperature $T_c = \theta_c T_m$ at the center of a short filament with leads at °K and the length $(2x)$ of the filament.

θ_c	$(x/a)_{\theta_c}^{\theta_0}$	θ_c	$(x/a)_{\theta_c}^{\theta_0}$	θ_c	$(x/a)_{\theta_c}^{\theta_0}$
0.005	0.7325	0.4	1.2065	0.94	2.031
.01	.8262	.5	1.2510	.95	2.118
.03	.9221	.6	1.3077	.96	2.225
.05	.9704	.7	1.3905	.97	2.365
.1	1.0401	.8	1.5280	.98	2.565
.2	1.1154	.85	1.6399	.99	2.912
.3	1.1645	.9	1.802	.995	3.261
		.92	1.899	.999	4.074

The effect of lead losses on characteristics. If all the filament were at the actual maximum temperature, T_c , the value H_c of any property for the whole filament would be

$$H_c = 2h_c x = 2ah_c(x/a)_{\theta_c}^{\theta_0}. \quad (53)$$

h_c is the value of the property in question for 1 cm of filament at temperature T_c . The ratio of the actual value for the whole filament, H , to the hypothetical value is H/H_c . The value of this ratio when $\theta_0 = 0$ we designate as $(H/H_c)_0$. If $n > 4$, H is independent of θ_0 for constant θ_c for all the practical range. Hence, applying Eq. (53)

$$H = 2ah_c(x/a)_{\theta_c}^{\theta_0}(H/H_c)_0. \quad (54)$$

H , and hence H/H_c , is a function of n , the temperature exponent of the property in question. In Fig. 3, ordinates $(H/H_c)_0$ are plotted against abscissae $(x/a)_{\theta_c}^{\theta_0}$ for constant values of n (the full lines). The scale for $(x/a)_{\theta_c}^{\theta_0}$ at the top, and the scale for θ_c on the bottom may be used interchangeably. They correspond as in Table IX.

For a given filament, knowing x , a , and θ_0 , $(x/a)_{\theta_c}^{\theta_0}$ is determined from Fig. 2. Fig. 3 then yields $(H/H_c)_0$ for the value of n corresponding to the property in question. H may then be found from Eq. (54).

For $n \leq 4$, H is not independent of θ_0 . For $n = 1.2$, the resistance-exponent, the dotted lines at the top of Fig. 3 give the value of H/H_c [not $(H/H_c)_0$] for constant values of $\tau_0 = \theta_0/\theta_c$. Note however that this is still given in terms of the abscissa $(x/a)_{\theta_c}^{\theta_0}$.

For values of x/a less than 1.0, and hence not in Fig. 2, H/H_c is constant at the value for $x/a = 1.0$.

It is to be remarked that for $T_c < 1000^\circ\text{K}$ none of the given data apply accurately, nor is the temperature distribution accurate. This is because of the uncertainty in the value of λ here.

Limits of long filament case. Table X gives the smallest value of $(x/a)_0^{\theta_c}$ for which the errors in H/H_c made in applying the long filament instead of the short filament case are less than the percentage at the head of the column. The errors of course depend somewhat on the value of n for the property under consideration. A (+) after the value of n indicates that the long filament case gives too large a value of H/H_c , or of H ; that is, too

Fig. 3. Full lines $(H/H_c)_0$ for constant n against $(x/a)_0^{\theta_c}$ and θ_c . Dotted lines H/H_c for $n=1.2$ constant τ_0 against $(x/a)_0^{\theta_c}$ and θ_c .

small a value of B_1 . In the neighborhood of $n=5$ the sign of the error changes. For $n=1$ (temperature distribution) the long filament case gives too high temperatures, even when the cooling effects of the two leads are added.

Lead temperatures may be found with sufficient accuracy for most cases from Table III of Part I. For high accuracy or for very short filaments Eqs. (36) and (39) may be applied directly, using Eq. (55).

TABLE X. Errors in H/H_c made in assuming a filament to come under Part I. This table gives approximately the smallest value of $(x/a)_0^{\theta_c}$ for which the error made by that assumption is less than the percentage given at the head of the column.

n	1 percent	5 percent	n	1 percent	5 percent
1.0 (+)	1.9	1.6	10 (-)	2.8	2.3
1.2 (+)	1.9	1.7	15 (-)	2.9	2.6
4 (+)	1.9	1.8	20 (-)	3.0	2.7
5 (\pm)	1.6	1.6	30 (-)	3.2	3.0
7 (-)	2.3	2.0	40 (-)	3.3	3.0

Computation of temperature distribution. Eq. (30) holds with a new constant of integration determined by the condition $\phi = ad\theta/dx = 0$ when $\theta = \theta_c$ (the maximum temperature):

$$1.3\phi^2 = \theta^{-0.8}(\theta_c^{2.6} - 0.4\theta_c^{6.5} - \theta^{2.6} + 0.4\theta^{6.5}). \quad (55)$$

The integration in Eq. (52) is best carried out by series approximations. *Case I.* $\tau = \theta/\theta_c$ is small

$$(x/a)_0^{\theta_c} = \theta_c \int_0^{\tau} d\tau/\phi. \quad (56)$$

Expressing Eq. (55) in terms of τ , then expanding $1/\phi$ by the binomial theorem and integrating the resulting series term by term

$$(x/a)_0^{\theta_c} = 0.8144A^{0.5}\theta_c^{0.1}\tau^{1.4} [1 + 0.175A\tau^{2.6} + 0.0795A^2\tau^{5.2} - 0.0354A\theta_c^{3.9}\tau^{6.5} + \dots] \quad (57)$$

where $A = 1/(1 - 0.4\theta_c^{3.9})$.

In Eq. (57) $\tau^{9.2}$ has been neglected. If $\theta \leq 0.6\theta_c$ the error is less than 1 percent. If in this series we set $\theta_c = 1$, we get the series of Eq. (33) of Part I. *Case II.* $\sigma = 1 - \tau = (\theta_c - \theta)/\theta_c$ is small and θ_c is also small.

Eq. (55) may be expanded in terms of σ to give

$$\phi^2 = 2\theta_c^{1.8}\sigma(1 - \theta_c^{3.9})(1 - \sigma)^{-0.8} [1 - 0.8\sigma(1 - 2.438\theta_c^{3.9}) + 0.16\sigma^2(1 - 24.78\theta_c^{3.9}) + 0.016\sigma^3(1 + 229\theta_c^{3.9}) + \dots].$$

Terms of the form $(1 - b\theta_c^{3.9})/(1 - \theta_c^{3.9})$ were expanded by the binomial theorem, and $\theta_c^{7.8}$ and higher powers neglected. Expanding $1/\phi$ and integrating

$$(x/a)_0^{\theta_c} = \theta_c \int_0^{\sigma} d\sigma/\phi = \theta_c^{0.1}(1 + \frac{1}{2}\theta_c^{3.9})(2\sigma)^{0.5} [1 - 0.33\theta_c^{3.9}\sigma - 0.024\sigma^2(1 - 10\theta_c^{3.9}) - 0.0034\sigma^3(1 + 5.38\theta_c^{3.9})]. \quad (58)$$

This is accurate when σ^4 and $\theta_c^{7.8}$ may be neglected in comparison with unity. At $\theta_c = 0.56$ this error is about 1 percent.

Case III. σ is small and θ_c large.

Let $z = 1 - \theta$ and $z_c = 1 - \theta_c$. z and z_c are both small. Expanding (55) by the binomial theorem

$$1/\phi = 0.5064(1 - 0.4z - 0.12z^2 + \dots)(z^2 - z_c^2)^{-0.5} [1 + 1.0167C_1 + C_2 + \dots]. \quad (59)$$

where

$$\begin{aligned} C_1 &= (z^3 - z_c^3)/(z^2 - z_c^2) \doteq z [1 + (1/2)(z_c/z)^2] \\ C_2 &= 1.5504C_1^2 - 0.930(z^4 - z_c^4)/(z^2 - z_c^2) \\ &\doteq [0.621 + 1.008(z_c/z)^2]z^2 \end{aligned}$$

substituting, multiplying Eq. (59) out, collecting like terms and integrating

$$(x/a)_{\theta_c}^{\theta_c} = \int_{z_c}^z dz/\phi = 0.5064(1+0.852z_c^2) \operatorname{arc} \cosh (z/z_c) + 0.3123(z^2 - z_c^2)^{0.5} \\ + 0.2574z_c \operatorname{arc} \cos (z_c/z) + 0.0239z(z^2 - z_c^2)^{0.5} \quad (60)$$

This series is good if $\theta_c \geq -0.7$; $\theta \geq 0.5$.

Case IV. θ_c is nearly unity.

We may choose z small enough for series (60) to converge, but at the same time much larger than z_c . The small quantity z_c then has little effect on the integral from 0 to $1-z$. To evaluate this integral we may neglect z_c entirely and use Eq. (35) of the long filament case, which, by the choice of the integration constant, gives the value of $(x/a)_0^{\theta}$. z as chosen above is sufficiently small for this series also to converge. Adding Eqs. (35) and (60), expressing $\operatorname{arc} \cosh (z/z_c)$ as a logarithm and $\operatorname{arc} \cos (z_c/z)$ as a series, and remembering that z is much larger than z_c , we obtain

$$(x/a)_{\theta_c}^{\theta_c} = 0.5757 - 1.16596 \log_{10} z_c + 0.4043z_c + 1.9z_c^2. \quad (61)$$

The coefficient of the last term was chosen empirically so as to compensate for the missing terms. Note that the result is independent of the specific value of z , as long as it has such a value as to make the derivation valid.

Thus we can obtain $(x/a)_0^{\theta}$ by Case I and $(x/a)_{\theta_c}^{\theta_c}$ by Case II or III. These two methods overlap in the admissible values of θ except for intermediate values of θ_c , when neither Case II nor Case III is very good. Numerical integration was used for accurate results in this region. The value of $(x/a)_0^{\theta_c}$ may be obtained by Case IV or by the formula

$$(x/a)_{\theta_c}^{\theta_c} = (x/a)_0^{\theta_c} + (x/a)_{\theta_c}^{\theta_c}.$$

Table VII and Fig. 2 were obtained by the above methods.

Filament characteristics. Assuming as in Part I that the value of the property in question varies as the n th power of the temperature, we have

$$H = 2h_c \int_0^x (T/T_c)^n dx = 2ah_c J \quad (62)$$

where

$$J = (1/\theta_c^n) \int_0^{\theta_c} \theta^n d\theta/\phi - (1/\theta_c^n) \int_0^{\theta_0} \theta^n d\theta/\phi. \quad (63)$$

If $n > 4$, θ^n becomes rapidly smaller with decreasing θ . Hence we may neglect the second integral to obtain

$$J = (1/\theta_c^n) \int_0^{\theta_c} \theta^n d\theta/\phi. \quad (64)$$

From Eqs. (53) and (62)

$$(H/H_c)_0 = J/(x/a)_0^{\theta_c}. \quad (65)$$

There are two limiting cases to be considered.

Case I. θ_c is small.

We may neglect $\theta_c^{6.5}$ in Eq. (55). Introducing $\tau = \theta/\theta_c$ we obtain from Eqs. (63), (53), (62), (52), and (55)

$$H/H_c = \frac{\int_{\tau_0}^1 \tau^{n+0.4} d\tau (1-\tau^{2.6})^{-0.5}}{\int_{\tau_0}^1 \tau^{0.4} d\tau (1-\tau^{2.6})^{-0.5}}.$$

The value of θ_c has cancelled out. If $\tau_0 = \theta_0/\theta_c$ is held fixed, then H/H_c is independent of θ_c . Hence in Fig. 3 the values for $x/a < 1.0$ are the same as those given for $x/a = 1.0$.

Case II. θ_c is large.

As θ_c approaches unity we get the transition from the short filament to the long filament case. When $z_c = 1 - \theta_c$ can be neglected entirely, Eqs. (64) and (43) give

$$(x/a)_{0^c}^{\theta} - \theta_c^n J = B_1. \quad (66)$$

From Eq. (62)

$$H = 2a h_m (\theta_c^n J).$$

Thus when (66) is satisfied the value of H increases in direct proportion to the increase of length. This is because the central portion, to which the increased length is added, is at practically constant temperature.

The degree to which Eq. (66) is satisfied is a measure of the approximation involved in assuming that the filament is long. To construct Table VIII the true values of J as found below were compared with the value calculated from Eq. (66). For $n=0$ the short filament temperature distributions were compared with those obtained from the long filament case by adding the cooling effect of the two leads.

Evaluation of J . If θ_c and hence $D = 0.4 \theta_c^{3.9} (1 - 0.4 \theta_c^{3.9})^{-1}$ is small, we set $y = (\theta/\theta_c)^{2.6}$ in Eq. (64) and obtain, using Eq. (55)

$$J = \theta_c^{0.1} M (1/5.2)^{1/2} (1 - 0.4 \theta_c^{3.9})^{-1/2} \quad (67)$$

where

$$M = \int_0^1 y^p dy (1-y)^{-1/2} [1 - Dy(1-y^{3/2})(1-y)^{-1}]^{-1/2} \quad (68)$$

and $n = 2.6p + 1.2$. M may be expanded as a power series in D

$$M = G_0 + (1/2)G_1 D + (3/8)G_2 D^2 + (5/16)G_3 D^3 + \dots \quad (69)$$

where

$$G_k = \int_0^1 y^{p+k} (1-y)^{-1/2} [(1-y^{3/2})(1-y)^{-1}]^k dy. \quad (70)$$

Each of these integrals may be expanded in terms of $u=1-y$, and then integrated by means of gamma functions.

$$\begin{aligned}
 G_0 &= \pi(-1/2)\pi(p)/\pi(p+1/2) \\
 G_1 &= \frac{3\pi(-1/2)\pi(p+1)}{2\pi(p+3/2)} [1 - (1/8)(p+5/2)^{-1} \\
 &\quad - (1/32)(p+5/2)^{-1}(p+7/2)^{-1} + \dots] \\
 G_2 &= \frac{9\pi(-1/2)\pi(p+2)}{4\pi(p+5/2)} [1 - (1/4)(p+7/2)^{-1} \\
 &\quad - (1/64)(p+7/2)^{-1}(p+9/2)^{-1} + \dots] \\
 G_3 &= \frac{27\pi(-1/2)\pi(p+3)}{8\pi(p+7/2)} [1 - (3/8)(p+9/2)^{-1} \\
 &\quad + (3/64)(p+9/2)^{-1}(p+11/2)^{-1} + \dots].
 \end{aligned} \tag{71}$$

As θ_c and D become larger the series of Eq. (69) does not converge rapidly. A better series may be obtained by setting

$$M = G_0(1 - g_1 D - g_2 D^2 - \dots)^{-1/2} \tag{72}$$

and determining the value of each g_i in terms of the G_k 's by expanding Eq. (72) and equating coefficients with Eq. (69).

If θ_c is very small, D may be neglected entirely. For the case $n=0$, Eqs. (69), (71), (67) give

$$J = (x/a)_{\theta_c}^{\theta_c} = 1.309(\theta_c)^{0.1}. \tag{73}$$

This is useful in determining the smaller values of Table VII.

When $0.9 \leq \theta_c < 1$ even series (72) does not give accurate results. The values of J here were determined by means of Simpson's rule. The difficulties due to the infinite integrand at $\theta = \theta_c$ were avoided by an integration by parts.

If n is small, θ_c may not be neglected as in Eq. (64). The most important case is $n=1.2$ (the exponent for resistance). The values of J may be found from Eq. (63), the first integral being evaluated by the methods above, and the second integral by a series similar to that of Eq. (57). This holds over the useful range $\theta_0 \leq 0.6 \theta_c$.

A similar method might be used for other small values of n . The calculations for the second integral may be simplified by neglecting $\theta^{0.5}$ in Eq. (55). At $\theta_0 = 0.6 \theta_c$ the error made thus is less than 3 percent for any short filament ($\theta_c \leq 0.94$). Since this integral is a correction term, the approximation is justified. By substituting $u = 1 - 0.4\theta_c^{3.9} - (\theta/\theta_c)^{2.6}$, the integral is reduced to a form which may be evaluated in terms of elementary functions for $n=1.2, 2.5, 3.8, 5.1$ and 6.4 . Interpolation may be used for intermediate values of n .

For $n \geq 4$ Eq. (64) is valid, unless high accuracy is desired. When $n=10$, $\theta_c=0.7$, $\theta_0=0.5$, the error is less than 1 percent.

Experimental checks. Several lamps were made up to test the short filament theory by experiment. Filament L was a straight filament 1.6 cm long, $D=0.0256$ cm, cut from a length of wire that had been aged 24 hours at 2400° . It was welded to nickel leads 5 cm long, $D_L=0.254$ cm. The temperature distribution along this filament was measured by means of an optical pyrometer mounted on a carriage that could be moved along a horizontal scale which gave the position of the pyrometer accurately to 0.001 inch. The pyrometer had previously been calibrated against a standard lamp.

The curves in Fig. 4 show the temperature distribution for three different currents. The solid lines indicate the observed values, and a comparison of T_c in each case with the corresponding value of T_m listed in the corner of

Fig. 4. Temperature distribution for filament L , $D=0.0256$ cm, $2x=1.6$ cm, wire aged throughout its length. Experimental and theoretical curves.

the graph, shows that the center of the filament is greatly cooled by the leads; in other words, filament L is a "short filament."

The temperature distribution was calculated from the short filament theory and the results shown in the curves marked by triangles. In Curve 1 where $\theta_c=0.912$ and $T_m-T_c=234^\circ$, the agreement with experiment is fairly good. In the more nearly extreme cases of Curve 2 where $\theta_c=0.836$, $T_m-T_c=408^\circ$, and Curve 3 where $\theta_c=0.687$, $T_m-T_c=725^\circ$, the temperatures given by the theory are too high. We attribute this departure from the observed values to an error in the value of λ at the cool ends of the filament. The heat conductivity of tungsten is not accurately known at temperatures below incandescence, and if we have used values of λ in this range that are too low, so that the calculated temperature gradient near the leads is too steep, the resulting T_c will be too high. An error from this source becomes important

only when the short filament theory is put to the severe test of predicting T_c in cases where T_c is much less than T_m .

Since T_c must be known before either the voltage or the candle-power of a filament can be calculated, the following empirical addition to the theory has been devised, to be used in those cases in which T_c can be determined only by calculation. To compensate for the error that results from using values of λ that are too low, we proceed as if the length of the filament were shortened by an amount Δx such that the heat loss by conduction will be increased above Q_λ , the value corresponding to λ , by an amount $\psi = 4Q_\lambda\Delta x/(\pi D^2)$. Q_λ is given by Eq. (37) which for $\theta_0 = 0.24$ becomes approximately

$$Q_\lambda = 0.6654 A \theta_c (1.812 \cdot 10^{-5} T_m^{1.3}) \quad (74)$$

It has already been pointed out, in connection with the derivation of Eq. (40), that changes in θ_0 have little effect on the factor 0.6654. θ_c supplies approximately the factor by which Q_λ must be reduced when the integration in Eq. (36) is carried only to θ_c instead of to 1. The term in brackets is given in Table V. Values of ψ derived from the data of Fig. 4 are given in Table XI. They were calculated using those values of Δx which made the theoretical and observed curves coincide at 1500°; the theoretical curves are indicated by crosses. ψ is tabulated as a function of T_0 , since the error is greater at low lead temperatures.

TABLE XI.

$T_0 =$	300°	400°	500°	600°
$\psi =$	471	367	263	159

From Table V and Table XI one can calculate

$$\Delta x = \pi D^2 \psi / (4Q_\lambda) \quad (75)$$

and subtract Δx from the actual half length x of the filament before calculating T_c . This correction applies to calculations of T_c only, and the maximum values to be used are $0.15x$ for leads in air, and $0.22x$ for leads in liquid air.

Fig. 5 is a plot of the volt-ampere characteristics of filament G, 1.928 cm in length, $D = 0.0103$ cm. The curves labelled air, using the bottom scale for voltage are for the bulb at room temperature, 300°K. The curves labelled liquid air, using the top scale for voltage, are for the bulb immersed in liquid air.

The course of the liquid air observations for low voltages is interesting. For $450^\circ < T_c < 1200^\circ$ and $T_m \approx 2,000^\circ$, the current decreases with increasing voltage. This phenomenon has been obtained with all short filaments which have been tried in liquid air.

Thus for one value of the current there are in some cases three possible values of the central temperature of the filament. With a low temperature the heat generated is small and so the small temperature gradient is sufficient to carry away the heat and maintain equilibrium. Likewise, with a

higher central temperature the heat generated is greater and the larger temperature gradient is necessary to preserve stability. Hence it is possible that all three central temperatures may be stable. The phenomenon may be explained in more detail by assuming that below $1,200^\circ\lambda$ is larger than the value given by Eq. (24). Analysis shows that the general form of Eq. (73), which gives $(x/a)_0^{\theta_c}$ for small θ_c , is

$$(x/a)_0^{\theta_c} \propto \theta_c^{(1+k-\rho)/2}. \quad (73a)$$

If k , the thermal conductivity exponent, is less than 0.2, then by Eq. (73a) the temperature distribution curves of Fig. 2 will cross near $\theta=0$ and $x/a=1$. Thus $(x/a)_0^{\theta_c}$ and hence also T_m and A decrease with increasing θ_c for small values of the latter. This is essentially the phenomenon observed above.

Fig. 5. Volt-ampere characteristics of filament G , $D=0.0103$ cm, $2x=1.928$ cm, wire aged throughout its length. Experimental and theoretical curves.

To obtain the calculated voltages, marked by crosses on the curves in Fig. 5, a correction of $0.6\Delta x$ subtracted from x was found sufficient to compensate for the decreased voltage drop along the ends of the filament due to the lower temperature which we assume to exist in this region. Thus for $n=0$, (temperature distribution) the correction is Δx ; for $n=1.2$ it is $0.6\Delta x$; and for higher values of n no correction is needed.

Example of the calculations. To illustrate the method of calculating lead losses, consider filament G running at a current of 1.295 amps. From $D=0.01030$ cm we find $D^{3/2}=0.001045$, $A/D^{3/2}=1239$, thence $T_m=2222^\circ(12)$. Table I gives by interpolation $a_0=0.400$, whence, as $D^{1/2}=0.1015$ we find from Eq. (2) that $a=0.406$. To determine the lead junction temperature, we find in Table III that $(\Delta T)_0=59^\circ$ and hence with $l=5$ cm and $D_L=0.254$ cm Eq. (4b) gives $\Delta T=59^\circ$. Thus $T_0=359^\circ$, and by interpolation in Table XI $\psi=410$. Table IV gives $(1.812 \cdot 10^{-5} T_m^{1.3})=0.4064$, so that from Eq. (75) we have $\Delta x=0.100$ cm if we put $\theta_c=1$. The half-length $x=0.964$, therefore $x'=x-\Delta x=0.864$. Dividing by $a=0.406$ we have $(x'/a)_{\theta_0}^{\theta_c}=2.128$. Since $T_0=359^\circ$ we find θ_0 by dividing by T_m , and have $\theta_0=0.1616$. We then find

the point of coordinates 2.128, 0.1616 on Fig. 2, and drawing through it a curve parallel to the given curves we obtain the intercepts $\theta_c = 0.959^{18}$ and $(x'/a)_0^{\theta_c} = 2.220$. Multiplying θ_c by T_m we find $T_c = 2131^\circ$.

Eq. (54) shows that the voltage of a short filament is given by

$$V = A(H/H_c)8xp_c/(\pi D^2) \quad (76)$$

ρ_c is the resistivity at T_c and is $61.12 \cdot 10^{-6}$ ohm cm^{18} . To find H/H_c we must first obtain τ_0 by dividing 359° by T_c to obtain 0.168. From Fig. 3 for abscissa $(x'/a)_0^{\theta_c} = 2.220$ we find $H/H_c = 0.766$. We substitute for x in Eq. (76) the corrected value $x - 0.6\Delta x = 0.904$ and obtain $V = 1.315$ volts. The experimental value was $V = 1.330$.

To find the candle power we use Eq. (54) to give

$$\text{Candle power} = H_c = 2aDC_c'(H/H_c)_0(x/a)_0^{\theta_c} \quad (77)$$

C_c' , the specific candle power of tungsten at T_c , is found to be 47.3 international candles $\text{cm}^{-2(18)}$. From Eq. (18) using T_c instead of T_m we find the effective value of n to be 12.53. From Fig. 3 for abscissa $(x'/a)_0^{\theta_c} = 2.220$ we then find $(H/H_c)_0 = 0.362$. $(x/a)_0^{\theta_c}$ is obtained from $(x'/a)_0^{\theta_c}$ by multiplying by $x/(x - \Delta x)$ to give 2.477. We thus obtain $H_c = 0.355$ international candles. We did not measure the candle power in this instance, but in other instances similar calculations of candle power gave results that were in good agreement with experimental values.

Discussion of experimental checks. In ordinary practice the ends of a filament are "unaged," that is, they can never be heated to the temperature which a filament must once have before the properties become those of "aged" tungsten. It is known⁶ that heating tungsten wire for one minute to a temperature of about 1500° causes the cold resistance to be lowered 15 to 20 percent, and presumably the heat conductivity would be increased at the same time by about the same amount. The filaments used for experimental checks were made from wire that had been previously aged throughout its length, in order to obtain uniform results, for the properties of unaged wire vary from sample to sample and depend on the history of the filament. It has been shown that in the case of aged tungsten the heat conductivity at the cool ends of the filament is higher than the values used in the theory. But where the filament is unaged in this region, the heat conductivity is lower than in the case of the aged filament which tends to restore λ to the values used in the theory so that in general the short filament theory may be used without the correction Δx to calculate lead losses from filaments that are made in the ordinary way.

¹⁸ Where θ_c comes out to be less than 0.95 it is well to substitute θ_c equal to the calculated value instead of unity in Eq. (74), and thus arrive at a second approximation for Δx from Eq. (75).

THE ABSORPTION COEFFICIENT FOR SLOW ELECTRONS
IN CADMIUM AND ZINC VAPORS

BY ROBERT B. BRODE

DEPARTMENT OF PHYSICS, UNIVERSITY OF CALIFORNIA

(Received January 27, 1930)

ABSTRACT

The variation with the electron velocity of the absorption coefficient, α , or the effective collision cross-section has been measured in the vapors of cadmium and zinc and found to follow a curve of the type previously found for mercury. The cadmium curve has a maximum at about 40 volts, $\alpha=130$, and a minimum at about 25 volts, $\alpha=126$, followed by a steady rise with decreasing velocity to the limit of accurate measurements, 1 volt, $\alpha=700$. The zinc curve has a very flat maximum at about 50 volts, $\alpha=76$, a minimum at about 36 volts, $\alpha=74$, followed by a steady rise to $\alpha=500$ at 1 volt. The magnitudes of the maximums are in the order: Cd, $\alpha=130$; Zn, $\alpha=75$; and Hg, $\alpha=60$. Other related properties of these atoms, such as the molar refractivity and the critical potentials, show this same irregularity in order.

THE measurement of the absorption coefficient for electrons in the noble gases, Ar, Kr and Xe,¹ has shown that the shape of the curves obtained is the same for all three of these. Similar measurements in the vapors of the alkali metals² have shown that these elements also have a characteristic type of curve. Mercury has been studied by Brode,^{3,7} Maxwell,⁴ Beuthe,⁵ and Jones.⁶ All of these observers except Beuthe have found a curve with values of the absorption coefficient in excellent agreement. Cadmium and zinc were also studied at the same time with the first measurements of mercury.³ These observations were shown by subsequent experiments⁷ to be unreliable, due to secondary and reflected electrons which were present in the form of apparatus used for the first measurements.

The apparatus, Fig. 1, used for the measurements of cadmium and zinc was of the same design as that described in the measurements of mercury.⁷ About half of the measurements in cadmium vapor were made with the apparatus used for the mercury measurements. The mean radius of the path was 15 mm and the final slit was 0.5 mm wide. The rest of the observations in cadmium were made with an apparatus in which the mean radius of the path was 10 mm and the width of the final slit 1.0 mm. All of the measurements in zinc were made with this same apparatus.

papers. The pressure of the gas was obtained from the vapor pressure at the temperature of the lower furnace which contained the supply of metal. This pressure was corrected for thermal effusion and the observations were

Fig. 2. The absorption coefficient α for electrons in cadmium vapor as a function of the velocity of the electrons.

reduced to 0°C and 1 mm of Hg pressure. The constants of the vapor pressure equation were taken from those given in the International Critical Tables.⁸

⁸ International Critical Tables, Vol. III, p. 205.

These constants for zinc and cadmium are much more accurately determined than those for the alkali metals. The principle source of uncertainty in the values of the absorption coefficients is not due to the vapor pressure constants in this case but to the determination of the temperature. From the uncertainty in the temperature, not over 2°C , the resulting absorption coefficients might be in error by about 5 percent. Small differences in the temperature could be measured to 0.1°C .

Samples of the metals were used which were over 99 percent pure. These were distilled several times in vacuum and finally into the apparatus, which had previously been baked at 500°C for several hours, and the metal

Fig. 3. The absorption coefficient α for electrons in zinc vapor as a function of the velocity of the electrons.

parts glowed by an induction furnace. This treatment was effective in removing the gases absorbed in the cadmium and zinc as measurements of the absorption coefficient were constant over a period of two months in a closed apparatus.

By plotting the log of the ratio of the current at the end of the path to the current from the slit in the cylinder, S_e , against the pressure, a straight line was obtained. The slope of the line gave the value of the absorption coefficient for unit pressure. Figs. 2 and 3 show the resulting values of the absorption coefficient for cadmium and zinc. Each point is the result of measurements at from 3 to 5 different pressures. Due to increasing leakage currents above 300°C , the data obtained with zinc were not as consistent as

those obtained with cadmium. The data taken with the two different experimental arrangements in cadmium are shown on the graph and are seen to be in excellent agreement. In the upper right portion of each graph the low velocity measurements are plotted. In cadmium the measurements were taken to 0.5 volts but, due to the leakage currents at the higher temperature used with zinc, the measurements could not be extended to 1.0 volt in zinc. There is an indication that the absorption coefficient in cadmium ceases to rise as rapidly below one volt as above one volt.

The opening of the final slit determines the maximum angle through which an electron may be deflected without being measured as absorbed. In

Fig. 4. The absorption coefficient α for electrons in cadmium, zinc and mercury vapors as a function of the velocities of the electrons.

cadmium two systems of slits and chambers were used with different limiting angles but the values of the absorption coefficient were not changed. Measurements by several observers on mercury⁷ gave results that are quite consistent although the chambers used were geometrically quite different. This would indicate that the number of electrons scattered through small angles is only a small fraction of the total number of scattered electrons. These results are not in agreement with the measurements of Arnot⁹ which indicate that a large fraction of the electrons of 82 volts velocity in mercury vapor are scattered in small angles. An apparatus with an adjustable aperture is being constructed to test this point.

⁹ Arnot, Roy. Soc. Proc. A125, 660 (1929).

In Fig. 4 the curves for cadmium and zinc are compared with that for mercury. The values of α for mercury⁷ have been changed from those due to vapor pressure data in Landolt and Börnstein's tables used in the original report to the data given in the International Critical Tables¹⁰ from which the vapor pressure data for cadmium and zinc were also taken. This involves an increase of about 10 percent in the values of α . The character of all the three curves is the same; a very large effective cross-section for slow electrons which decreases rapidly with increasing velocity to a minimum, then rises slightly to a faint maximum followed by a steady decrease with further increase in velocity.

The curves indicate that cadmium is the largest of the three, zinc is next, and mercury is the smallest. This is the order of size to be expected rather than that of increasing atomic weight. The classical scattering of electrons due to the polarization of the atom by a passing electron was shown by Zwicky¹¹ to give the right order of magnitude for the absorption coefficients in the noble gases at velocities above the maximum in the curves. The absorption coefficient was proportional to the molar refractivity. The molar refractivities for these elements are Cd = 20.0 Zn = 14.6, and Hg = 13.7. This same agreement between the absorption coefficients and molar refractivity is found in the alkali vapors. The effective size of an atom is also indicated by its ionization potential. Helium, with the highest ionization potential, has one of the smallest effective cross-sections of any observed atom while caesium, with the lowest ionization potential, has the largest effective cross-section. The ionization potentials of the elements studied in this paper are Cd 8.9 volts, Zn 9.4 volts and Hg 10.4 volts. In the curves of elements not in the same row of the periodic table and therefore of different shape, it is not always easy to designate one as larger than the other. In general, however, it seems to be true that the magnitude of the absorption coefficient or the effective collision cross-section of an atom is proportional to the molar refractivity and inversely proportional to the ionization potential.

COHESION IN MONOVALENT METALS

By J. C. SLATER

JEFFERSON PHYSICAL LABORATORY, HARVARD UNIVERSITY

(Received January 27, 1930)

ABSTRACT

The theory of metallic structure, of Sommerfeld, Heisenberg, and Bloch, is carried far enough to explain cohesive forces, and calculations are made for atoms with one valence electron, particularly metallic sodium. The numerical results, though rough, are in qualitative agreement with experiment. It is found that the forces in general are of the same nature as those met in ordinary homopolar binding, discussed by Heitler and London; except that the purely electrostatic force from penetration of one atom by another is relatively more important, the valence effect from the exchange of electrons relatively less important, than in diatomic molecules.

As a preliminary to the calculation, the relations of the methods of Heisenberg and of Bloch are discussed, and it is shown that they are essentially equivalent in their results when properly handled. Remarks are made both about conductivity and ferromagnetism. In connection with conduction, it is shown that a definite meaning can be given to free electrons, that they are necessary to conduction, and that a method can be set up for computing their number, which is rather small compared with the number of atoms. Ferromagnetism is discussed in connection with a recent paper of Bloch. It is shown that a metal like an alkali cannot be ferromagnetic, for atoms at such a distance that the interatomic forces keep the metal in equilibrium, are too close to be magnetic. For ferromagnetism, rather, it seems necessary to have one group of electrons responsible for cohesion, and another group, of smaller orbit and therefore relatively farther apart, producing the magnetism; a situation actually found only in the iron group and the similar groups.

I. INTRODUCTION

A CRYSTAL of a metal is an enormous molecule, with electronic energy levels depending on the positions of all the nuclei, just as the electronic energy of a diatomic molecule depends on the internuclear distance. In this paper, in which we are interested in cohesive forces, we must find this energy of the lowest state in terms of the size of the crystal. We limit ourselves to geometrically similar arrangements of the nuclei, with changing scale. From the minimum of the curve, we find the heat of dissociation, grating space, and compressibility of the metal. But also we can investigate the wave function of this lowest state, and obtain information about the electric and magnetic properties of the metal. In this way we are naturally led to a discussion of the calculations of Heisenberg¹ and of Bloch on these subjects; in order to be sure that we really understand the arrangement of energy levels, we discuss the relationships of their methods, and arrive at a consistent picture combining them.

¹ W. Heisenberg, *Zeits. f. Physik* **49**, 619 (1928);
F. Bloch, *ibid.* **52**, 555 (1929).

As for the results, one naturally asks first, what are the forces holding a metal together? Are they ordinary attractions on account of penetration of atoms, or valence forces, or electrostatic forces of ionic attraction, or van der Waals forces, or some special sort not found in other cases? This question cannot be answered categorically; no doubt all the forces are simultaneously present, and the problem is to find the relative magnitudes. The tentative result at which we arrive is that the simple penetration of one atom by another is the most important part of the effect. But valence effects are also present, although weakened by having the valences shared by many neighbors, and are responsible for a considerable fraction of the attraction. Although these actual magnitudes may not be verified by more accurate calculation, still we have discussed the problem in enough detail so that the general relations can be understood in any case.

The other question one will ask is, what is the situation of the electrons in the metal? Can one give a meaning to the question, how many free electrons are there? The answer, from whichever side we look at the question, seems to be the same. Most of the valence electrons are at any time attached to their atoms. These electrons cannot take part in conduction; they could do it only by having a whole file of such electrons simultaneously jump to the next atom in line, a most unlikely occurrence. But a few electrons at any time—calculation suggests a few percent—will be detached from their atoms, leaving an equal number of positive ions behind them; and they are what, by all rights, one should call free electrons. These electrons, and the positive ions left behind, can take part in conduction. First, the free electrons can move easily from one atom to the next. Second, a bound or associated electron on one of the atoms next a positive ion can jump to that ion, leaving its own atom ionized. We are thus led precisely to the dual theory of conduction, by free and by associated electrons, which Professor Hall² has suggested and elaborated. When we look at the metal by the method of Heisenberg, these results become clear. In that method, a wave function consists of the assignment of electrons to atoms. We find that we must go beyond Heisenberg, in assigning sometimes two electrons to one atom, sometimes none, instead of always one; for we need such states to solve the problem of the stationary states of the metal. That is, we introduce free electrons. And when we consider transitions from one state to another, it is easy to see that these transitions can result in conduction only when such free electrons are present. On Bloch's scheme, where we describe directly the velocity, rather than the position, of the electrons, it is less easy to see the relation; but here too one can show that, if there are no free electrons, the velocities of all electrons must compensate, so that there is no net current. Since this paper is not primarily about conduction, we do not go into these points with any detail.

The only metals specifically treated are those with one valence electron per atom, and that in an *s* state; that is, the alkalis. And it is assumed that they can be replaced by single valence electrons moving in non-coulomb

² E. H. Hall, *Proc. Nat. Acad.*, 1920-1921.

fields. This can be easily justified. It is to be noted that the other metals are more complicated, not merely by having more electrons, but by having them in p or d orbits, thus introducing new degeneracies. The actual calculations of cohesion have been carried through for sodium, with satisfactory results. They are only done roughly, however; the primary purpose of this paper is to make clear the general relations, rather than to attempt accurate calculations. The work is being carried further by Dr. Bartlett, and I wish to thank him for help on some of the calculations used in this paper. The work described here has been done while the writer was on leave, working in Leipzig. He wishes to thank Professor Heisenberg for his courtesy in extending the privileges of his laboratory, and for a number of illuminating conversations on the subject of the paper; and also to thank Harvard University for granting leave, and the Guggenheim Foundation for the assistance of a fellowship.

2. COMPARISON OF HEISENBERG'S AND BLOCH'S METHODS

The problem of a metal must be attacked by perturbation theory, and the unperturbed functions which we use can be set up in two quite different ways, one used by Heisenberg, the other by Bloch, either giving us a finite set of unperturbed functions. We regard the perturbation problem in the following way: we seek those linear combinations of these functions which, in the sense of the variation method, form the best approximations to solutions of Schrödinger's equation. This problem is solved by computing the matrix of the energy operator with respect to these functions, and solving the equations

$$\sum_k (H(i/k) - \delta(i/k)W)S(k) = 0$$

for the coefficients $S(k)$ to be used in making the linear combinations, and the energy values W of the resulting terms. (The term $\delta(i/k)$ must be given a slightly different form if the unperturbed functions are not orthogonal). This differs from the more conventional method: there one starts with an infinite, complete set of unperturbed functions, instead of our finite set, but solves only as a power series in the non-diagonal terms of the energy matrix, breaking off after the second power in all ordinary applications. It resembles more closely the quite different method ordinarily used with degenerate systems, where one takes only very few unperturbed states, but correctly solves the problem of combining them. For a nearly degenerate problem like the present one, with a great many states near together, the conventional method of developing in series will not work well, for the series do not converge well, and we are forced to use something like the present method. The justification comes simply from the assumption that the lowest states can be well approximated by such a linear combination of Heisenberg's or Bloch's functions (which correspond to having the atoms in their normal states). Surely this is not exact; for better results we should have to consider also the excited states of the atoms. But also certainly it is a fair approximation for the lowest states of the metal.

Heisenberg's functions, amplified in a simple way, form good approximations when the crystal is extended, for they are derived from the separated atoms. Bloch's functions on the other hand come by analogy with the free electron theory of Sommerfeld, and are good approximations when the crystal is compressed. The actual solutions of the perturbation problem are of course linear combinations of either Heisenberg's or Bloch's functions, not individual ones, and one gets the same final result whichever set one starts with (for the two sets of functions can be written as linear combinations of each other). But the fact that in the limiting cases the functions of one of the two sets become rather good approximations can be used, along with interpolation, to derive the general nature of the real stationary states. This comparison is made in the present section, and is illustrated by the interesting case of H_2 , where the calculations can be made exactly. At the outset, we must recognize two facts: first, that we must amplify Heisenberg's method by including polar states, to make it general enough to agree with Bloch's and to permit conductivity; second, that although Bloch has the proper set of functions, he has nowhere attempted to solve the perturbation problem, but has merely taken his unperturbed functions as being correct, which amounts to getting the energy to the accuracy of the conventional "first order perturbations."

The first step in either Heisenberg's or Bloch's method, as we apply them, is to write an approximate solution as a product of functions of the individual electrons. Heisenberg takes, for these separate functions, the wave functions of electrons attached to individual nuclei; the number of such functions is the product of the number of nuclei, multiplied by the number of different sets of quantum numbers we consider for an individual nucleus. If we restrict ourselves to s states, there are then only two states per nucleus, corresponding to the two orientations of the spin. For nucleus a , we denote these two³ by $u_\alpha(a/x)$, $u_\beta(a/x)$, and we have such a function for each nucleus $a \ b \ \dots \ n$. Bloch takes, on the other hand, combinations of these functions:

$$u_\alpha(klm/xyz) = \sum_{g_1 g_2 g_3} e^{2\pi i(kg_1/G_1 + lg_2/G_2 + mg_3/G_3)} u_\alpha(g_1 g_2 g_3/xyz),$$

where $g_1 g_2 g_3$ are the coordinates of a particular nucleus, $G_1 G_2 G_3$ the dimensions of the rectangular crystal, and $u_\alpha(g_1 g_2 g_3/xyz)$ the wave function (as used by Heisenberg) for an electron moving around the nucleus situated at $g_1 g_2 g_3$. The function with k, l, m represents an electron, in general moving in the direction k, l, m , but pausing at the various atoms on the way. There are as many sets k, l, m allowed as there are atoms in the crystal; for larger k, l, m the function proves to be merely a repetition of one already counted.

³ We use here for convenience in writing Pauli's notation u_α, u_β for the spin, rather than the more explicit but more cumbersome notation $u(n/x_i) \delta(m_s/m_{si})$ used in a previous paper. See J. C. Slater, Phys. Rev. **34**, 1293 (1929). The method used in the present paper is described, as applied to atoms, in the paper referred to; it should be understood that, although we speak here of using Heisenberg's and Bloch's methods, our actual procedure is quite different from that of these authors.

Now we actually set up the product of functions mentioned in the previous paragraph: we pick one out and let it be a function of the coordinates x_1 of the first electron, a second for the coordinates x_2 of the second, and so on to the n th, and multiply them all together. By the exclusion principle, no function can be chosen more than once. Then we form an antisymmetric combination, by permuting the indices of the electron coordinates, and adding the permuted functions with appropriate signs, obtaining essentially a determinant. These antisymmetric functions are the ones with which we start our perturbation calculation. Many such functions can be set up: there are $2n$ functions of a single electron, of which only n are to be chosen for each antisymmetric function, so that there are $(2n)!/(n!)^2$ different functions. Our perturbation problem is that of finding which linear combinations of these functions most nearly satisfy the wave equation. We may note the restriction of Heisenberg's method as he uses it; he does not include polar states. That is, he does not allow for example the two functions $u_\alpha(a/x)$, $u_\beta(a/x)$ to appear together in any product. This greatly limits the number of functions; but although the terms obtained by it certainly represent the lowest energy levels, since it requires energy to form a positive and a negative ion from two neutral atoms, we do not make this limitation.

Having set up the unperturbed functions, we next make linear combinations of them, by the method described in a previous paragraph. This process can be simplified by using a property of the spin. Every unperturbed function has a certain definite component M_s of spin along the axis, equal to $(n_\alpha - n_\beta)/2$, where n_α is the number of electrons with positive component of spin, n_β the number with negative. If now we neglect the magnetic interaction between the spins and the orbital motion, the problems with each value of M_s can be handled separately: the components $H(i/j)$ from a function with one value to a function with another are zero. The states with a given M_s include, as one readily sees, all those states whose total spin S is equal to or greater than M_s (for just these S 's can be so oriented, on the vector model, as to give a component M_s along a fixed axis). Thus by solving each such problem, and comparing, we can identify the spin of each term.⁴

The two methods can be illustrated by the case of H_2 . Here there are $4!/(2!)^2 = 6$ different wave functions. On Heisenberg's method, the four functions for an individual electron can be symbolized by $(\alpha\alpha)$, $(\beta\alpha)$, $(\alpha\beta)$, $(\beta\beta)$; two of these are to be picked out for each antisymmetric wave function. Thus the six are $(\alpha\alpha)(\alpha\beta)$; $(\alpha\alpha)(\beta\alpha)$, $(\alpha\beta)(\beta\beta)$; $(\alpha\alpha)(\beta\beta)$, $(\beta\alpha)(\alpha\beta)$; $(\beta\alpha)(\beta\beta)$. They are arranged, first, by M_s : the first has the value 1, the next four the value 0, and the last -1. Thus the terms consist of one triplet and three singlets. Among the four terms with $M_s = 0$, the first two are polar (and not considered by Heitler and London, or Heisenberg), the last two are non-polar. Immediately one finds that the sum of these non-polar functions is the component of the triplet. We are then left with three functions: the

⁴ This is essentially the method used in the paper already quoted. It has already been applied by Bloch to problems in the theory of metals. See F. Bloch, *Zeits. f. Physik*, **57**, 545 (1929).

two polar ones, and the difference of the non-polar ones, from which to find our three singlets. The difference of the polar ones is antisymmetric in the nuclei, giving one state; their sum, and the difference of the non-polar functions, give two functions symmetrical in the nuclei, between which we finally solve the simple perturbation, resulting now in a quadratic secular equation, and obtain the two remaining singlet states. The energy levels as a function of the distance of separation are plotted in Fig. 1. The energy level of the lowest, $^1\Sigma S''$, is almost exactly as given by Heitler and London, but its wave function contains quite an appreciable contribution from the polar state. The triplet is just the repulsive state of Heitler and London. The other two levels are essentially polar. They go at infinite separation to the energy of $H^+ + H^-$, greater than the other limit by the ionization potential less the electron affinity of H (this rough approximation gives $-\frac{1}{4}Rh$ for the electron

Fig. 1. Energy levels of H_2 .

affinity, so that the terms go to $5/4Rh$). The lower of these has a minimum; it is presumably the polar part which, by combination with other functions, leads to the experimentally known B state of the molecule. We notice that at large separations the functions behave just like Heisenberg's (extended) unperturbed functions: a triplet and a singlet are non-polar, and go to the lower energy; while two singlets are polar, and go to the higher level.

Next we consider Bloch's method for the same problem. His functions for one electron, for this case, are

$$u_a(0/x) = u_a(a/x) + u_a(b/x)$$

$$u_a(1/x) = u_a(a/x) - u_a(b/x),$$

with similar functions for β . (These do not follow quite directly from the general formulas given above; Bloch's functions must be slightly modified for finite systems, for they apply rather to infinite but periodic ones.) The discussion of multiplicity given above goes through without change, if we only substitute 0, 1 for a, b . We can easily show by direct calculation

that the resulting unperturbed antisymmetric functions are linear combinations of those found by Heisenberg's method. For example, for $M_s=1$, there is only one function by either method, so these must be identical, except for a numerical factor. By Heisenberg's method the function is

$$u_\alpha(a/x_1)u_\alpha(b/x_2) - u_\alpha(b/x_1)u_\alpha(a/x_2).$$

By Bloch's it is

$$\begin{aligned} & u_\alpha(0/x_1)u_\alpha(1/x_2) - u_\alpha(1/x_1)u_\alpha(0/x_2) \\ &= [u_\alpha(a/x_1) + u_\alpha(b/x_1)][u_\alpha(a/x_2) - u_\alpha(b/x_2)] \\ &\quad - [u_\alpha(a/x_1) - u_\alpha(b/x_1)][u_\alpha(a/x_2) + u_\alpha(b/x_2)] \\ &= -2[u_\alpha(a/x_1)u_\alpha(b/x_2) - u_\alpha(b/x_1)u_\alpha(a/x_2)]. \end{aligned}$$

We can set up the whole perturbation problem in these functions; and the solution can be carried out as easily as before, leading of course to just the same answers. The interesting question now is, how closely do Bloch's individual functions approximate the correct ones, for small values of R ? The functions are respectively as follows: a singlet with both electrons in the state 0; a singlet and triplet with one in the state 0, the other in the state 1; and a singlet with both in the state 1. The state 0 corresponds to the lowest vibrational state on Sommerfeld's theory, the state 1 to the next higher one, so that the first state has on the simple interpretation only the zero-point vibrational energy, the next two have each one quantum, and the last two. Examination of the actual wave functions shows that they agree quite closely with the functions of Bloch: the lowest one is made, it is true, by combination of the (00) and (11) states, both being S^N , but the coefficient of the first is about eight times as large as that of the second, when R is such that the energy is at its minimum. The next two are made up of the (01) states. The highest is about eight parts of (11) to one of (00). The energies also show, for high compression, the behavior expected: the two states which should have one quantum of vibrational energy draw together, and the one with two quanta is just about twice as far above the lowest state as those with one. Even the spacing of these levels is just about what would be calculated on Sommerfeld's theory for an electron vibrating in a region the size of the molecule. Thus we see that Bloch's unperturbed functions form fairly good approximations to the real functions for the compressed state, as Heisenberg's do for the extended state.

We can now return to the general case, and make use of the fact that Heisenberg's functions approximate the real wave functions well for large separations, Bloch's for small. First, for the extended system, the energy is the ionization energy, on account of having many ions as well as neutral atoms. For a metal, it requires about 6 volts to form a positive and negative ion from two neutral atoms. Thus if all the atoms were ionized, we should have $n/2$ such pairs, or an energy per atom, or per electron, of about 3 volts. This measures the extension of the group of terms, for large R . It is a simple problem in permutations to find the number of terms of each multiplicity

with each energy value in the limit. The one term of highest multiplicity will approach the lowest limit, for large R ; it must be entirely nonpolar, for all spins point in the same direction, so that no two electrons can be in the same atom. For the next lower multiplicity, only one electron has a reversed spin; it is the only one which can be in an atom with another electron, so that there can be just one pair of atoms ionized. Following out, we easily see that terms of lower and lower multiplicity, in the limit of large R , lie higher and higher, and at the same time are more and more spread out. They spread in such a way that there are terms of each multiplicity way down to the bottom limit, although not to the top. As we shall see later, for R large but not infinite, in the normal case, the really lowest terms have small spins; but near them are many terms with large spin.

For the compressed system, the arrangement is as given by Bloch's theory. The total extension of the group of terms increases with $1/R^2$; for ordinary values of R , it is of the order of the mean zero-point energy, times n , which is decidedly larger than 3 volts $\times n$. Thus not only do the curves tend upward for decreasing R , giving repulsive energy levels, but they are definitely doing this at the actual size of the metal. The general physical interpretation of this repulsion is obvious: the valence electrons act here approximately as a perfect gas, and the energy levels are those of such a gas as it is compressed adiabatically against gas pressure, the energy varying therefore as $V^{-2/3}$ or as $1/R^2$. Here the terms of high multiplicity lie in the center of the pattern; those of lower spin also average in the center, but are more and more spread out. Since the terms of high spin are so low for large R , but not for small R , they must be even more repulsive than the others. The possibility seems very remote that any terms except those with very low multiplicity could be so low as to have minima, and come into the question for the normal state. We see that for cohesion we are interested only in the very lowest fraction of the whole set of terms. These terms almost all will go to the lowest energy level at infinite separation; they become in this limit non-polar. And the accuracy with which one can compute the lowest states of H_2 from Heitler and London's non-polar functions suggests that here too this may be possible. Accordingly for our actual calculation of these lowest states, we shall use Heisenberg's method with only non-polar functions. We shall find here, as we expect from our qualitative discussion, that the terms of low multiplicity really do lie below, some of them being attractive; while those of high multiplicity are repulsive, the highest spins lying highest. Finally we shall consider the effect of polar terms, and conclude that it is really small on the low energy levels, although not on the wave functions; for it is the polar character of the wave functions which makes conductivity possible.

3. ELECTRIC AND MAGNETIC PROPERTIES

Conductivity. In the introduction we have mentioned the interpretation of electric conduction on Heisenberg's and on Bloch's scheme. One notices that a single one of Bloch's functions implies conduction—the diagonal term

of the momentum matrix is different from zero—whereas with Heisenberg's functions we must have a continual change from one stationary state to another. But it is particularly important to notice that, without polar states, or free electrons, no conduction is possible; we cannot set up combinations of non-polar states with a resultant momentum. For example, with two electrons, we can set up an arbitrary non-polar function $c_1u(a/x_1)u(b/x_2) + c_2u(b/x_1)u(a/x_2)$. If now we compute the momentum, whose operator is $\hbar/2\pi i(\partial/\partial x_1 + \partial/\partial x_2)$, the only possibly significant terms are the cross terms, like

$$\begin{aligned} & c_1c_2 \frac{\hbar}{2\pi i} \int u(a/x_1)u(b/x_2) \left(\frac{\partial}{\partial x_1} + \frac{\partial}{\partial x_2} \right) u(b/x_1)u(a/x_2) dv_1 dv_2 \\ &= c_1c_2 \frac{\hbar}{2\pi i} \left\{ \int u(b/x_2)u(a/x_2) dv_2 \int u(a/x_1) \frac{\partial}{\partial x_1} u(b/x_1) dv_1 \right. \\ & \quad \left. + \int u(a/x_1)u(b/x_1) dv_1 \int u(b/x_2) \frac{\partial}{\partial x_2} u(a/x_2) dv_2 \right\}. \end{aligned}$$

On account of the penetration of one atom by the other, the integrals $\int u(b/x_2)u(a/x_2) dv_2$ are not zero. The integral $\int u(a/x_1)(\partial/\partial x_1)u(b/x_1) dv_1$ is also different from zero. But it is exactly cancelled by $\int u(b/x_2)(\partial/\partial x_2)u(a/x_2) dv_2$, as one can show by Green's theorem, so that the whole is zero. On the other hand, if we set up a polar combination like $c_1u(a/x_1)u(a/x_2) + c_2u(b/x_1)u(b/x_2)$, we again get two terms, but now they add, and give a current. As another example, we can take the term of maximum multiplicity in any system. In this term, we have seen by Heisenberg's scheme that each atom has just one electron, so that we expect no conduction. But in Bloch's scheme, each value k, l, m has just one electron. Since each such value is balanced by one with $-k, -l, -m$, having opposite momentum, the total momentum is zero, and there is again no current.

We can now see the importance of considering exactly the wave functions, as well as the energy levels, of the lowest state. In the ordinary low states there will, of course, be no current. But near the lowest state, if there is to be conductivity, there must be combinations of polar states, having a current, which are assumed in the presence of a field, and whose added energy comes simply from the kinetic energy of the electrons and the self-induction. Such states are possible only on account of the presence of positive and negative ions, with the resulting free and associated electron conductivity.

Magnetism. The lowest state of H_2 is the non-magnetic $^1\Sigma$, and we have found such a situation in general. In the region where the lowest states have their minimum, the metal must surely be in a compressed state, Bloch's arrangement of energy levels must be a good approximation, and the states of large spin must lie very high. We are thus led to the quite general conclusion that the outer electrons, which are largely if not entirely responsible for both cohesion and conduction, cannot produce ferromagnetic effects. If a metal is to be ferromagnetic, there must then be other electrons than these

outer ones which are responsible for it, and these others must have smaller orbits, so that at the equilibrium distance of the outermost ones, the inner ones will be relatively further apart, and can be treated as an extended rather than as a compressed system. It is a very attractive hypothesis to suppose that in the iron group the existence of the $3d$ and $4s$ electrons provides in this way the two electron groups apparently necessary for ferromagnetism; for it is only in the transition groups that we have two such sets of electrons, and this criterion would go far toward limiting ferromagnetism to the metals actually showing it.

We next ask just how such inner electrons could be ferromagnetic. Certainly the general trend of the terms of high spin to the low energy values at large R is an essential part of the question: there will be terms of large spin near the lowest level. Bloch⁵ has discussed the problem, concluding that for large R 's the terms of high spin actually lie lower than those of smaller spin (he does not specifically discuss the dependence on R , but his energy formulas all contain it parametrically). This conclusion, however, is not correct; Bloch has merely computed diagonal values of the energy, with respect to his functions, and for large R these by no means form approximations to the actual energy values. From the correct treatment of the problem as we have given it, it is plain that at all R 's there are terms of low multiplicity as low as those of high spin, or lower. It may be, however, that the mere presence of so many low terms of high multiplicity may be enough, on account of their high *a priori* probability and large number, to insure that the terms of large spin should be well represented at ordinary temperatures, even though there are low terms of zero spin, and so produce ferromagnetism. If, however, this should prove on calculation not to give the right effect, we should be led to consider Heisenberg's assumption that the normal order of terms is inverted in ferromagnetic atoms, the terms of high multiplicity lying lowest. He has shown by a general argument that electrons of large total quantum number (which the $4s$ electrons of iron have) have an exchange integral of the opposite sign to that found in hydrogen, so that the order of the non-polar terms would be reversed. This we should fit into our scheme in the following way: although this exchange integral is anomalous at large R , it presumably changes sign and becomes normal at smaller R ; for first, Heisenberg's general argument only applies at large R ; and second, our condition that the energy levels should approach those of Bloch at small R , with the terms of large spin lying high, seems quite general. Thus we should assume that the terms at small R lie as in Fig. 1: but that at a considerable value of R , there is a crossing over (in this case the ${}^3\Sigma A^N$ crossing and lying under the ${}^1\Sigma S^N$), described by a change in the sign of the exchange integral K used in the next section from negative to positive. By assuming the existence of an inner group of electrons with these properties, we seem to secure a consistent picture of ferromagnetism. On the other hand, of course it is always possible that ferromagnetism is connected with the fact that the valence electrons of iron have an orbital angular momentum different from zero.

⁵ F. Bloch, *Zeits. f. Physik*, 57, 545 (1929).

4. COHESION

We are now prepared to begin the actual calculation of the lowest stationary states. We make several simplifications, which we later remove. First, we consider only non-polar states, in Heisenberg's scheme, and disregard exchange integrals except between adjacent atoms; this is the approximation also made by Heisenberg. Finally, for the present, we consider a linear lattice, n atoms uniformly spaced along a line, rather than a space lattice. Our problem, of course, is to compute the matrix of the energy with respect to the wave functions we have chosen, and then solve the problem of making proper linear combinations. The computation of the matrix is simple. By a fundamental formula of the previous paper mentioned above, the diagonal components are a sum, first, of the energies of the separate atoms, which we need not consider; next, a sum over all adjacent pairs, as the pair of atoms a and b , of integrals $J(a/b)$, which is essentially the diagonal energy E_1 of Heitler and London; finally, a sum over all adjacent pairs which have the same spin, of terms $-K(a/b)$, where K is the exchange integral E_2 of Heitler and London. Further, it is easy to show that all non-diagonal terms are zero, except those for which the distributions in the two states differ only by the exchange of an adjacent α and β ; in such cases, the term is $-K$. In the normal case, to which we shall refer specifically, J and K as functions of R are both negative, K numerically greater than J . But in Heisenberg's case, K must be taken to be positive for large R , although presumably negative for small R .

To illustrate by H_2 , we have one state with both spins parallel; then the energy is $J-K$. Next we have the problems with one parallel, the other anti-parallel; there are two such states (the two polar ones being omitted). Each has the diagonal energy J , and the non-diagonal energy between them is $-K$. Thus the equations for the linear combinations are

$$\begin{aligned}(J-W)S(1)-KS(2) &= 0 \\ -KS(1)+(J-W)S(2) &= 0,\end{aligned}$$

giving energy values $W=J\pm K$, the first evidently being the singlet, the second the component of the triplet.

In the general case, the computation of the matrix is no more difficult; the real problem is the solution of the linear equations for the S 's. We cannot do this exactly; but we adopt two methods of approximation, one holding for larger spins, the other for smaller spins. We first discuss the former.

Method for large spins. First we take the problem where all spins are parallel, $n_\alpha=n$, $n_\beta=0$. Here there is but one state. Since with our linear lattice there are $(n-1)$ adjacent pairs, and all spins are parallel, the energy is simply $(n-1)J-(n-1)K$. Since J and K are normally both negative, but K numerically greater than J , this is a positive energy for all values of R , and results in a repulsive term. For Heisenberg's case, on the other hand, K is positive, and this term is attractive. Next we take the problem $n_\alpha=n-1$, $n_\beta=1$. There are now n unperturbed wave functions: the one electron β can

be attached to any of the n atoms. We number the functions by the number of the atom where the electron is, only decreased by $\frac{1}{2}$: we have $u_{1/2} \cdots u_{n-1/2}$. Each of these functions will have the diagonal energy $(n-1)J - (n-3)K$, since two of the adjacent pairs now have opposite spins, except for the two functions $u_{1/2}$ and $u_{n-1/2}$ where our β electron is at an end of the lattice, and the energy is $(n-1)J - (n-2)K$. Also, all non-diagonal terms will be zero except those between terms of adjacent number, as for example between those symbolized by

$$\begin{aligned} & \cdots \alpha \alpha \alpha \beta \alpha \alpha \alpha \cdots \\ \text{and} & \cdots \alpha \alpha \alpha \alpha \beta \alpha \alpha \cdots, \end{aligned}$$

and which differ by just one interchange of an α and β . As a result, the perturbation equations will be

$$\begin{aligned} & [(n-1)J - (n-2)K - W]S\left(\frac{1}{2}\right) - KS\left(\frac{3}{2}\right) = 0 \\ & -KS\left(\frac{1}{2}\right) + [(n-1)J - (n-3)K - W]S\left(\frac{3}{2}\right) - KS\left(\frac{5}{2}\right) = 0 \\ & -KS\left(\frac{3}{2}\right) + [(n-1)J - (n-3)K - W]S\left(\frac{5}{2}\right) - KS\left(\frac{7}{2}\right) = 0 \\ & \cdots \cdots \cdots \\ & -KS\left(n - \frac{3}{2}\right) + [(n-1)J - (n-2)K - W]S\left(n - \frac{1}{2}\right) = 0 \end{aligned}$$

These equations are easily solved; they occur, for example, in the problem of a string weighted at equal intervals,⁶ the S 's being the displacements of the weights. To solve, we merely assume $S(k) = \frac{\cos}{\sin}(\alpha k)$. The first and last equations give boundary conditions. They become like the others if we introduce an $S(-\frac{1}{2})$ and $S(n+\frac{1}{2})$, the first equation becoming

$$-KS(-\frac{1}{2}) + [(n-1)J - (n-3)K - W]S(\frac{1}{2}) - KS(\frac{3}{2}) = 0,$$

and if we further set $S(-\frac{1}{2}) = S(\frac{1}{2})$ and $S(n+\frac{1}{2}) = S(n-\frac{1}{2})$. These are then the boundary conditions; and to satisfy them we must take

$$S(k/p) = \cos p\pi k/n, \quad \text{where } p=0, 1, \cdots, n-1.$$

Now we substitute this form in our difference equations; and we get for W

$$-K\left(\cos \frac{p\pi}{n}(k-1) + \cos \frac{p\pi}{n}(k+1)\right) + [(n-1)J - (n-3)K - W(p)] \cos \frac{p\pi k}{n} = 0,$$

from which in each case

$$W(p) = (n-1)J - (n-3)K - 2K \cos \frac{p\pi}{n}.$$

⁶ See, for example, Rayleigh's "Theory of Sound."

We now have the transformation coefficients $S(k/p)$ and the energy values $W(p)$ for the rotation of axes to the p th stationary state; the W 's are the exact energy levels. They are evidently distributed between the values $W(0) = (n-1)J - (n-1)K$, and $W(n-1) = (n-1)J - (n-3 - 2 \cos \pi(n-1)/n)K = (n-1)J - (n-5)K$, almost, for large n . Obviously $W(0)$ is the energy of the level of highest multiplicity, which we have found before. Thus the levels $1 \cdots (n-1)$ are those of next to highest multiplicity.

Next we take the problem with two electrons of spin β . There are $n(n-1)/2$ such terms: each of the two indistinguishable β 's can be on any one of the n atoms, so long as they are not on the same atom. Now it is convenient to denote states by the two atoms, say i and j (each going from $\frac{1}{2}$ to $n - \frac{1}{2}$) on which electrons β are. Our problem becomes analogous to that of a square membrane loaded at equally spaced points. The diagonal terms of the energy are all $(n-1)J - (n-5)K$, unless one of the β 's is at an end of the lattice, or unless the two β 's are adjacent. There are four non-diagonal terms for transitions from each wave function: for $i \rightarrow i \pm 1$, or for $j \rightarrow j \pm 1$. A typical equation can be written

$$\begin{aligned} & -KS(i, j-1) \\ & -KS(i-1, j) + [(n-1)J - (n-5)K - W]S(ij) - KS(i+1, j) \\ & -KS(i, j+1) = 0. \end{aligned}$$

This we satisfy by a product of cosine functions, $S(ij/pq) = \cos(p\pi i/n) \cos(q\pi j/n)$. We easily find that these exactly satisfy the boundary conditions when i or $j = \frac{1}{2}$ or $n - \frac{1}{2}$. There remains the condition when i is nearly equal to j . If $i = j \pm 1$, the diagonal energy is $(n-1)J - (n-3)K$, since the two β 's are together; on the other hand, since the β 's cannot be on the same atom, the coefficients $S(jj)$ and $S(j+1, j+1)$ vanish, so that only two transitions, rather than four, are possible. If now we define an $S(jj)$ and $S(j+1, j+1)$, we can make the equations of the same form as the general one, if only $S(jj) + S(j+1, j+1) = 2S(j+1, j)$. This furnishes our second boundary condition, which is evidently along the diagonal of our square "membrane." Unfortunately we cannot satisfy this condition exactly with our cosine functions; closer investigation shows that one must have much more complicated functions, with hyperbolic cosines, to satisfy it exactly, and one cannot carry the method through for the general case. Approximately, however, we can easily take care of our condition. If the p and q are not too great, so that the "wave-length" of the waves in our membrane is large, we can replace our condition by a differential one: it states that the amplitude at a point next the diagonal is the mean of the two adjacent values on the diagonal, and this very nearly means that the normal derivative of the function, at right angles to the diagonal, is zero. This we can satisfy by making our function symmetrical about the diagonal, or using $\cos(p\pi i/n) \cos(q\pi j/n) + \cos(q\pi i/n) \cos(p\pi j/n)$. We may expect this to hold best for small p and q , not so well for large values. It is clearly not right; for example, it yields $n^2/2$ functions, instead of the correct number $n(n-1)/2$.

Our function is an exact solution of the difference equations, if not of the boundary condition; and we find for the energy

$$W(p, q) = (n-1)J - (n-5)K - 2K \left(\cos \frac{p\pi}{n} + \cos \frac{q\pi}{n} \right),$$

where p, q go from 0 to $n-1$, but each pair is counted only once. The term of highest multiplicity comes from $p=q=0$; the $(n-1)$ terms of next highest value are those with either p or $q=0$, but the other not; the remaining terms are of multiplicity smaller by two.

This result can now be generalized without trouble: if we have many β 's, the energy levels are given by

$$W = (n-1)J - (n-1-2n_\beta)K - 2K \sum_{i=1}^{n_\beta} \cos \frac{p_i\pi}{n}, \quad p_i = 0 \cdots n-1.$$

The terms where one or more p_i 's equal zero are those whose total spin is greater than $(n_\alpha - n_\beta)/2$; those with all p_i 's different from zero are those whose total spin equals $(n_\alpha - n_\beta)/2$. The latter value is evidently enormously greater than the other: every spin has enormously more terms than any higher spin. Thus the terms of a given component of spin along the axis, and those of the same total spin, are approximately the same. We can at once find the distribution in energy of the terms of a given spin. They evidently cluster about the value $(n-1)J - (n-1-2n_\beta)K$; they are distributed about this value like the displacements of a point simultaneously acted on by a sum of n_β periodic vibrations of equal amplitudes but arbitrary phases. This gives, of course, approximately a Gauss distribution. The width of the distribution curve can be derived very easily: we compute the mean square deviation of the energy from its mean, $(W - \bar{W})^2 = 4K^2 [\sum \cos(p_i\pi/n)]^2$, the average being taken when each p varies independently from 0 to n . We can take this variation to be continuous rather than discrete. Then the product terms in the square of the sum of cosines all average to zero, the square terms average to $\frac{1}{2}$, and the result is $2K^2 n_\beta$. These results may be compared with those obtained by Heisenberg on the group theory, and which as Bloch has shown can also be found from the present method. In the notation of the present paper, putting the number of neighbors of each atom equal to 2, and leaving out the terms in J , Heisenberg finds

$$\begin{aligned} \bar{W} &= -(n - 2n_\beta + 2n_\beta^2/n)K \\ (\overline{W - \bar{W}})^2 &= 2K^2 n_\beta (1 - n_\beta/n)(1 + 2n_\beta/n - 2(n_\beta/n)^2). \end{aligned}$$

Our formulas agree with these exact ones to terms in n_β but no further, as we expect from the fact that our approximations hold only for small n_β . For small p 's, as we have seen, our results should be good even for large n_β ; for the case of ferromagnetism, when on Heisenberg's hypothesis the terms are reversed, these are the lowest terms, so that this result should be very useful here. In the normal case, however, the lowest terms are those of large p , and these are the ones we need for cohesion. About these lowest terms, we

can be fairly sure that they lie higher than the lowest ones we have found, or $(n-1)J - (n-1-4n_\beta)K$, since the mean lies higher than the mean we found. For zero spin, for example, we can be fairly sure that the term lies above $(n-1)J + nK$. But this value need not be a very good approximation; we actually find, by the method of the next section, that the lowest term for zero spin is about $(n-1)J + 0.290nK$. Fortunately even this has a positive coefficient for K , and is so an attractive rather than a repulsive term.

Method for zero spin. For zero spin, $n_\alpha = n_\beta = n/2$, and there are $n!/(n/2!)^2$ terms. We adopt quite a different method of classifying them. Before, most of the terms of a given n_β had nearly the same diagonal energy; but now the range of energy is large, from $(n-1)J$ for the state with alternating α 's and β 's so that there are no parallel spins, to $(n-1)J - (n-2)K$ for the state where all the α 's come at one end of the lattice, all the β 's at the other. With this large range, we find it convenient to classify terms by their diagonal energies; and we find as we should expect, that for the lowest states of the perturbed system we must consider most the low unperturbed states. We do not need to take into account all states: we find that approximately (though by no means exactly) the terms can be divided into a number of non-combining sets, and we set up one such set in the following way. We commence with the lowest state, of energy $(n-1)J$, where α 's and β 's alternate. Next we consider the $n-1$ states which combine with it, coming from interchanging one pair, and each having the energy $(n-1)J - 2K$, except those from the two end pairs, with energy $(n-1)J - K$. We leave these two out, retaining for our set the $n-3$ states which have the energy $(n-1)J - 2K$. Each of these has $n-3$ states with which it combines, coming from interchange of one of the $n-3$ adjacent pairs with opposite spins. Of these $n-3$, the two in which the new interchanged pair is next the one already interchanged have the energy $(n-1)J - 2K$; the one in which the pair already interchanged is changed back has the energy $(n-1)J$; the two where the end pair is interchanged have the energy $(n-1)J - 3K$; and the remaining $n-8$ have the energy $(n-1)J - 4K$. We retain for our set only these $n-8$ terms of energy $(n-1)J - 4K$. So we proceed, asking which terms combine with those already set up, and retaining just those whose energy is $-2K$ greater than for those with fewer interchanges. We find that a term of our set, with the energy $(n-1)J - 2pK$, has non-diagonal terms to p terms of the set of energy $(n-1)J - 2(p-1)K$ and to $(n-3-5p)$ terms of the set of energy $(n-1)J - 2(p+1)K$. Evidently so long as p is small, the terms we leave out of the set and yet which combine with terms of the set are comparatively few. It is only for the large p 's that we make serious error by leaving out these terms, and for large p the diagonal energy is high enough so that for the lowest states of the perturbed system these unperturbed states are unimportant. Thus we may reasonably believe that the low energy levels found by solving this restricted problem will be approximately some of the low levels of the actual problem. We can at least be sure of the following: by the variation principle, they can be no lower than the actual stationary states.

The other sets of non-combining terms which we can set up are easily described, and are of considerable physical interest. Instead of starting from the state with spins alternating, we start from a state where the spins alternate up to a given point; there the sequence is interrupted, and alternation commences again, so to speak, in the opposite phase, as

$$\cdots \alpha \beta \alpha \beta \alpha \beta \alpha \beta \alpha \cdots$$

With a few such interruptions in the course of the crystal, the energy is very little above the really lowest state; yet a great many individual interchanges would be required to pass to the lowest state. With such a state to start with, we proceed just as we did before, and construct a whole system of states; and the non-diagonal terms between this and the first system come only from high values of p , involving many interchanges, and can be neglected. Physically, at the interruption of phase, one essentially has a slight interruption of crystal structure. Our catalogue of all possible states of the metal includes not only that where it is one perfect crystal, but also where it is composed of many smaller crystals not perfectly joined together. Obviously each problem can be treated separately; physically it would take a very long time to change from one to the other. And obviously each problem will give us essentially the same set of energy levels.

We now take our set of wave functions, and try to solve the perturbation problem between them. For each value of p , we have many wave functions; and we look for those particular solutions for which all these functions have the same coefficient $S(p)$. Afterwards we shall show that we really find the lowest solutions this way. Then, remembering the number of transitions with non-diagonal term K from a given state, computed above, we have for a typical equation

$$-KpS(p-1) + [(n-1)J - 2pK - W]S(p) - K(n-3-5p)S(p+1) = 0.$$

This set of difference equations for the S 's is somewhat similar to what we had before; it also corresponds to a weighted string. But now the properties, and hence the wave-length, change from point to point, and we seek the various overtones. The equation is a close analogue to Schrödinger's equation, in many ways; the fact that it is a difference equation rather than a differential one is quite immaterial. To solve, we assume $S(p) = e^{\int \alpha dp}$, where α is to vary slowly with p . Then $S(p) = e^\alpha S(p-1)$, etc., so that we have

$$\begin{aligned} -Kp + e^\alpha [(n-1)J - 2pK - W] - e^{2\alpha} K [n-3-5p] &= 0, \\ e^\alpha &= \frac{-[(n-1)J - 2pK - W] \pm \{[(n-1)J - 2pK - W]^2 - 4K^2 p [n-3-5p]\}^{1/2}}{-2K [n-3-5p]}. \end{aligned}$$

The equation expresses e^α as a function of p , for any particular W . Now we must remember that there are essentially boundary conditions; the S 's must remain finite for $p=0$ and $p=\text{an extreme value}$. To tell how to apply this condition, we must investigate the solution we have found.

The ratio e^α of successive coefficients is real or complex, according as $[(n-1)J - 2pK - W]^2$ is greater than or less than $4K^2p[n-3-5p]$. Regarded as a function of p , the limiting cases, where the two are equal, come from $(n-1)J - W = 2pK \pm 2K[p(n-3-5p)]^{1/2}$. The right hand side, plotted as a function of p , forms an ellipse; the straight line represented by the left side intersects the ellipse in two points, or in none, depending on the value of W . The region of W where it intersects can be found by computing the maximum and minimum ordinates of the ellipse; that is, the values of $(n-1)J - W$ for which $(d/dp)(2pK \pm 2K[p(n-3-5p)]^{1/2}) = 0$. This gives $p = (n-3)/10 [1 \pm (1/6)^{1/2}] = (n-3) \times (0.0592, 0.1408)$. At these two limits, substituting, $W = (n-1)J + (n-3)K \times (0.290, -0.690)$. For values of W between these limits, there is a range of p for which e^α is complex, and the solution is oscillatory; outside this region, which is closed, the solution is in any case exponential. To satisfy our boundary conditions, now, we have a problem much like that with Schrödinger's equation in one dimension; and boundary conditions can be satisfied only if there is an oscillatory region. As a result, the actual energy levels of the problem must lie between the limits given. Closer examination shows that a "quantum condition" can be applied, and that between these limits there are just the number of energy levels there should be. We now have the lowest level: it lies arbitrarily close to our lower limit, or is

$$W = (n-1)J + 0.290(n-3)K,$$

as we stated in the last section. In this lowest state, we can show without trouble that the unperturbed wave functions with p near $0.0592(n-3)$ are represented most strongly. Thus the value of p is really quite small; relatively few pairs are interchanged, and we are safely in the region where we can treat the different systems separately.

We have solved our problem for the lowest state in which all terms of the same p have the same coefficient. We can now investigate the effect of removing this assumption, varying the coefficient of one function of a given p in one direction, varying the rest to keep the same total representation for functions of this p , and calculating the change in the energy. When we do this, we find the energy to be a minimum with respect to such variation; in fact, the changes of energy compensate each other to a higher order, showing that the problem is nearly degenerate with respect to these coefficients. Thus we may be rather confident that we have a good approximation to the lowest non-polar states. It is of course obvious that this method becomes worse as we go to higher states.

It is instructive to ask what ordinary perturbation theory would give us for the lowest state. The lowest unperturbed state has the diagonal energy $(n-1)J$; this represents the ordinary first order perturbation calculation. Now we pass to the second order calculation. The lowest state is not degenerate, so that we can use the power series development method. The next term in the expansion is $\sum_j (H_{ij}H_{ji})/(E_1 - E_j)$, summed over all excited states j . Now there are non-diagonal terms H_{1j} only to the $n-1$ states with $p=1$.

Thus the H_i 's are all equal to $-K$, and the energy differences are all given by $E_i = E_1 - 2K$. Thus we have as second approximation

$$W = (n-1)J + (n-1)\frac{K^2}{2K} = (n-1)J + \frac{1}{2}(n-1)K.$$

This differs from our result in having the factor $\frac{1}{2}$ rather than 0.290; we have only the first term of a series development, but it is reassuring that agreement is as good as it is. For finding the order of magnitude, we could use this term alone; we shall find this simple method useful with the space lattice.

Effect of polar states. One can make an estimate, by a method like that used here, of the effect of the polar states in depressing the non-polar ones, which alone we have considered so far. We can build up a series of states by starting with a given non-polar state; then removing one of the electrons to an adjacent atom, producing a positive and a negative ion; then removing a second; and so on. The series of states so found behave formally like those used above. If we solve the problem by the previous method, or by the second order perturbation method, we get a further depression of the lowest state, which again can be written as

$$(n-1) \times \frac{\sum \text{square of non-diagonal term}}{\text{energy difference}}.$$

The non-diagonal term which comes in here is presumably of the same order of magnitude as before, although it is a somewhat different integral. But the diagonal energy difference is now essentially an ionization energy, which is of the order of several volts, rather than the fraction of a volt that K is. Thus the effect on the energy is a number of times smaller than what we found before, and we can neglect it. It is not worth while calculating more accurately, in this approximation; for with H_2 , it appears that on account of the lack of orthogonality of the wave functions, the actual depression of the energy is very much less than this rough method would indicate, although the effect on the wave function is about what we should expect. One can reasonably believe for this reason that the polar states in the crystal depress the energy only very little. But we recall that their effect on the wave function is to introduce free electrons. By our rough method described above, we infer that the fraction of free electrons is of the order of 1 percent, for reasonable choice of the constants. This could easily be in error by a factor of 10 either way; but at least we see that a definite meaning can be attached to the number of free electrons, and that there is a definite procedure for calculating this number.

Normalization and orthogonality. We have not considered the lack of orthogonality of the wave functions, resulting in factors like the $1/1 \pm S$ of Heitler and London. When one tries to do this, one immediately strikes a difficulty which appears insurmountable: the factor in the denominator, instead of being like $1+S$, is like $1+nS+\dots$, where n is the number of

atoms, so that the term nS is enormous compared with unity. On examination of simple cases, it appears that the remaining terms, coming from other permutations than the simple interchange, are also important, in many cases the terms almost cancelling each other. Further, in every expression for energy, like the simple $(J \pm K)/(1 \pm S)$, there are more terms in the numerator, also of great importance. But the simple cases give no suggestion of how to treat the general case. The key to this difficulty comes from Bloch's method. For example, the term of maximum multiplicity has one function, which can be expressed either by Heisenberg's or Bloch's functions. But the difference is that Bloch's functions are really orthogonal, unlike Heisenberg's, so that we meet no such difficulty. Of course, the same terms occur, but now in the normalization of the individual functions. And the numerators, and denominators like $1 + nS + \dots$, appear as products of n factors, each of approximately a simple Heitler and London form; further, all but one or two of these factors of the denominator cancel against equal factors in the numerator, giving very simple results. Essentially the same method can be used with the other states; for this method is one for treating a determinant of Heisenberg's wave functions, and converting it into a determinant of Bloch's functions; and all of our wave functions are products of two such determinants. When we calculate in our case, it appears that the terms S will have small effect; we are roughly half way between the cases $1 + S$ and $1 - S$, and the effects of S nearly average out. This method at the same time gives the proper way of considering more distant pairs, as well as adjacent ones; these contribute the further terms in the numerators, as $J \pm K + \dots$. We see from the next paragraph that these more distant pairs are really quite important.

Method for space lattice. So far, we have spoken about a linear lattice of atoms, rather than a space distribution. We now extend this theory to a crystal; but we shall not carry it through in the same detail. We consider only the problem of zero spin, and use our second order perturbation approximation. Let us take the body-centered cubic lattice, which the alkalis have. The lowest unperturbed state of this lattice can be set up much as with the linear one: we let the electrons at the corners of the cubes have the spin α , those at the centers the spin β . Then each electron is surrounded by eight others of opposite spin, so that if we consider only adjacent pairs, the diagonal energy of this state is $4nJ$, where there are n electrons, $4n$ pairs. This lowest state now has non-diagonal terms, each equal to $-K$, to the $4n$ states obtained by interchanging an adjacent pair. Each of these states has two misplaced spins, each surrounded by 7 spins of the same sign, so that the energy has a term $-14K$. Thus for our perturbation problem, we have a non-diagonal energy $-K$, an energy difference $14K$, and $4n$ non-diagonal terms, so that the perturbed energy is $4nJ + (4nK^2/14K) = 4nJ + (2/7)nK$.

This formula is rather significant. We compare the energy with that of the lowest state of the diatomic molecule, $n=2$, which is $(n/2)J + \frac{1}{2}nK$. We observe that for the crystal the coulomb interaction, the term J , has a coefficient eight times as great: each atom has eight neighbors instead of one, each

penetrating. On the other hand, the valence term K has a coefficient only $2/7$, instead of $1/2$. The valence, so to speak, is spread out among all the neighbors, and weakened in the process. It is partly on this account that we can say that the coulomb interaction is the more important part of the cohesive force, in metals.

We have considered only those pairs with smallest separation, and they give a definite attraction. But in this lattice, there are not only the eight nearest atoms at distance R ; there are also six, in directions parallel to the edges of the cube, at distance of $1.155R$, and these have parallel spins, producing therefore a repulsion. In the diagonal energy, each pair will then contribute an energy $J-K$, a positive amount, so that the diagonal energy of the lowest state is $4nJ+3n(J(1.155R)-K(1.155R))$. The next higher diagonal energy also will differ from this not merely by $-14K(R)$, but also by an amount $12K(1.155R)$, because by interchange of two spins some of these repulsive terms are removed. Thus the lowest energy level, counting also these pairs, is

$$4nJ(R)+3n(J(1.155R)-K(1.155R))+\frac{4nK^2(R)}{14K(R)-12K(1.155R)}.$$

This results, on computation, in a much weakened attraction. If we were to consider in succession the effects of pairs at greater and greater distance, we should come in succession to attracting atoms with antiparallel spin, and repulsive ones with parallel, so that the successive approximations to the energy would oscillate, falling first above, then below, the true value.

Application to sodium. For the sodium crystal, approximate calculations have been carried out, to test these formulas. These were made by taking a simple analytical expression for the wave function of the valence electron of sodium, and computing the integrals J and K . The details of the calculation will not be given here. The first thing that one notices is that, for Na, J is several times larger in proportion to K than in hydrogen. It is this fact, taken together with the increased coefficient of the J term, that results in the importance of the coulomb term. It is also significant in connection with the question, why do the alkalies, and metals in general, form metallic lattices, while hydrogen does not? We can see the essential answer from our energy formulas of the previous page. For substances where J is the important term, the coefficient of J will be greater, and the energy lower, for the crystal than for the same number of atoms in diatomic molecules, and the crystal will be the stable form. For hydrogen, on the other hand, the valence term K is the important one. Here the coefficient in the molecular form is greater; and even if the metallic form of such a substance were stable in the sense of having a minimum of energy for some definite size, as seems quite possible, still the energy in the molecular state would be lower. The atoms in the crystal would tend to form pairs, resulting in a molecular lattice; the molecules would repel each other, and would be held together only by van der Waals forces, which have been neglected in this paper. This seems to be exactly what hydrogen does.

The numerical values for Na are approximately as follows. If we take only the adjacent pairs, the minimum comes at $R=4.9a_H$ approximately, rather seriously less than the correct value 7; this can partly be explained by the observation that the best atomic wave function for use in the crystal would be more extended than that determined from the free atoms, which are here used. The energy at this point comes out about -40 kg cal/gm mol, the coulomb term supplying about four fifths of this; the observed heat of vaporization is 26.4 kg cal, so that this gives, as we should expect, too large a value. If now we consider the repulsive pairs at distance of $1.155 R$, the situation is quite changed. In the first place, the energy is reduced from -40 to about -9 kg cal. When we remember that these two values are the first two terms of a series, whose value oscillates on both sides of the answer, it seems very reasonable that the final result should be not far below the experimental value. The problem of properly computing this energy must be done by the method, using Bloch's functions, described in the preceding section. In the next place, the minimum of the curve is greatly broadened: for quite a range of values, from $R=4.9$ (the previous minimum) to $R=7$, the energy stays about constant, the change of the attractive term being just about balanced by the relatively more rapid change of the smaller repulsive effect. (For smaller R 's, a situation can be found when the denominator $14 K(R) - 12 K(1.155 R) = 0$, so that the function becomes infinite; but this is without physical significance.) No doubt a persistence of this effect in the final answer helps to correct the improperly low grating space we have already found. It also is interesting in connection with the compressibility. The alkalies are remarkably compressible, and if we compute the compressibility for the case where only adjacent pairs are considered, the result is too small by a factor of 2 or 3. On the other hand, considering the next set of atoms, our very broad maximum would give much too great a compressibility. Here again it seems that our result may oscillate, perhaps approaching eventually something near the right value.

THE STABILITY OF METALLIC CRYSTAL LATTICES*

BY R. H. CANFIELD
NAVAL RESEARCH LABORATORY

(Received January 22, 1930)

ABSTRACT

The first sections of this paper are a partial repetition and amplification of Born's theory of homopolar crystal lattices, without, however, making any assumption about the law of force between atoms other than that the force is central and that diatomic molecules are possible. The mathematical work is supplemented with graphical illustrations. If the lattice is in equilibrium as regards (a) displacement of one atom, (b) unidirectional extension of the entire lattice, and (c) simple shear of the entire lattice, it is shown that each of these postulates leads to a restrictive condition on the symmetry and pattern of the possible lattices, thus accounting for the high symmetry actually observed. Finally if the equilibria *a*, *b*, *c*, are stable, there are three series of terms in W'' , corresponding to elastic constants, which must be positive. Making use of these series, it is shown that the lattice is likewise in equilibrium against motion of one portion *en bloc* relative to another portion and hence that "mosaic" crystals cannot be configurations of minimum potential energy.

INTRODUCTION

THE primary purpose of this paper is to determine whether there is any theoretical basis for the existence of a mosaic structure in crystals of metals or other crystals containing atoms of only one kind. This periodic inhomogeneity for which "mosaic" seems the best short equivalent, has been proposed by various workers¹ as accounting for the non-agreement between calculated and observed tensile strengths of crystals.

Zwicky¹ and his collaborators, e.g. Evjen,³ have made numerical calculations of the energy changes due to the formation of these mosaic structures in ionic lattices, and find that they are to be expected. Zwicky² has also published a general thermodynamic proof intended to apply to crystals of any kind, which the writer⁴ has criticized. The subject will be dealt with more fully in the closing paragraphs of this paper.

The present paper is an attempt to deal with the same problem, for metallic lattices only, in a rigorous manner.

The preliminary steps are elementary and a recapitulation of other work; but it is hoped that this feature may be of some value to others who have found Born's⁵ classical treatment "nicht ganz einfach zu lesen." The method and notation here introduced will be used by the writer in other papers.

FUNDAMENTAL STATEMENTS

Let us regard the atoms of a homopolar lattice as centers of mutual forces. Whatever wave-functions are in the background of this behavior we do not enquire. Neither do we concern ourselves with whether or not the atoms are charged. We merely assume that all the atoms are alike and that each two of them exert mutual forces on each other, independent of the presence of other atoms, such that at great distances they attract, and at very small distances they repel each other. At very great distances the force of attraction, and all its derivatives, vanishes. Finally, the mutual force has a potential.

We then represent the mutual energy W of two atoms in terms of their distance r by a curve like Fig. 1. In the absence of kinetic energy the two atoms will form a molecule, their centers being at a distance r_e . If they possess relative kinetic energy less than W_e , they will execute vibrations, the amplitude being represented by ρ . Due to the energy curve not being in general a parabola (i.e. not obeying Hooke's Law), these vibrations are neither iso-

Fig. 1.

chronous nor simply harmonic. The theory of the vibration of such an anharmonic oscillator is part of the theory of molecular spectra.

Our present problem is the application of this energy curve to those polyatomic molecules called crystals.

We next picture an aggregation of atoms in space occupying the points of a regular geometric space lattice and forming a crystal. For the time being we are not concerned with the exact configuration of this lattice. We fix our attention on a single atom of this lattice. We now construct spherical surfaces with this atom as center, such that all of the surrounding atoms fall on one or another of these surfaces. We select some distance, say the distance to the nearest neighbor atom, as a parameter and call it r_0 . The number of atoms at the distance r_0 we call $2n_1$. We designate the shells in the order of their radii by subscripts 1, 2, \dots , and their radii by k_1r_0 , k_2r_0 , \dots , k_ir_0 ; the number of atoms in the i th shell is $2n_i$.

Referring now to Fig. 2, an energy diagram for our selected atom, we put on it the ordinates corresponding to the various groups of neighbors at dis-

tances $k_i r_0$ and label each ordinate with the corresponding n_i . (It is plain that since the energy of each pair of atoms is W_i , the energy of each atom due to its neighbors at $k_i r_0$ is only $n_i W_i$ instead of $2n_i W_i$). Then the energy of one atom in the lattice is

$$U = \sum_{i=1}^{i=\infty} n_i W_i. \quad (1)$$

We may quite simply refer to n_i as the number of *bonds* of length $k_i r_0$ associated with each atom in the lattice.

Still assuming that the *type* of the lattice is fixed, it is next of importance to find how the crystal attains a configuration of a certain density. We are of course assuming that the atoms are at rest. Actually they are in vibratory motion but it can be shown that the amplitude of vibration is small com-

Fig. 2.

pared with r_0 and thus the fixed positions correspond pretty closely with the average positions of the atoms over a period of time. It is plain that a change in r_0 will result in a dilatation of the entire lattice to correspond; the equilibrium configuration will be that for which a small change in r_0 results in no change of energy. We therefore differentiate Eq. (1) as follows:

$$\partial U / \partial r_0 = \sum_i n_i \partial W_i / \partial r_0 = \sum_i n_i k_i W_i' = 0 \quad (2)$$

where $W_i' = [\partial W / \partial r]_{r=k_i r_0}$ and $\partial W / \partial r_0 = k_i W_i'$.

In more graphic terms, the array of ordinates in Fig. 2 is horizontally expanded or contracted, until, each ordinate being weighted with the corresponding number n_i , their sum is a minimum.

It will be of interest at this point to study the diagrams in Fig. 3. Diagram A is a plot of the number of bonds of length r or less than r for an atom in a face-centered cubic lattice; diagram B for a body-centered, and C for a simple cubic lattice. The dotted lines represent the same functions calculated on the assumption of uniformly distributed matter.

Several points of interest are at once apparent. There are almost always more bonds, shorter than any specified length, in a face-centered than in a body-centered cubic lattice, and more in the latter than in a simple cubic. It

is just this characteristic that is implied by the words "close-packing" applied to the two former types. Thus if atoms were rigid spheres attracting each

Fig. 3

other according to an inverse power of r , and therefore possessing an energy curve like Fig. 4, they would inevitably choose one of the configurations of

Fig. 4

closest possible packing, i.e., the face-centered cubic or close-packed hexagonal (practically equivalent).

Fig. 5

On the other hand, if the energy curve were like Fig. 5, they would choose the body-centered cubic type, since here there is room for the first two groups

of the body-centered lattice, containing 7 bonds and thus more negative potential energy than the face-centered type, which would have only one group containing 6 bonds in the deep loop of the diagram.

We thus already see a clue to the explanation of the different types of lattices. The expression for dU in terms of the second power of dr_0 yields a formula for the compressibility of the crystal. This is of course positive, since the configuration is one of stable equilibrium. The expression is

$$dU = \frac{1}{2} dr_0^2 \sum n_i k_i^2 W_i''.$$

EQUILIBRIUM AGAINST VARIOUS DISPLACEMENTS

1. *Displacement of a single atom.* We have already established the manner in which the atoms place themselves on a lattice of a certain type and with a certain density, i.e., equilibrium as regards dilatation and change of lattice type. It is next in order to study equilibrium against a displacement of one atom from its correct position, for if the lattice is not in stable equilibrium against such displacements, thermal agitation will destroy it. Referring to

Fig. 6

Fig. 6, the atom O under consideration is shown at the center of the i th sphere. Atom O suffers a displacement dx . The atoms in the shell i are arranged in groups p for which all the atoms in any group p lie in the same plane perpendicular to x . The number of atoms lying in the p th plane of the i th shell is n_{ip} and their bonds to O all make the same angle θ_{ip} with the X -axis. Evidently $\sum_p n_{ip} = 2n_i$. The change in energy dU due to the motion dx is then (only taking account of the atoms in shell i)

$$dU_i = \left(W_i' \sum_p n_{ip} \cos \theta_{ip} \right) dx.$$

For all the shells i we then have

$$dU = \left(\sum_i (W_i' \sum_p n_{ip} \cos \theta_{ip}) \right) dx = 0. \quad (3)$$

But we already have an equation (Eq. (2)) of the form

$$\sum_i A_i W_i' = 0,$$

and since these are two linear equations in the W_i' their coefficients must be proportional or else the coefficients of Eq. (3) must be zero. The latter is the only possible alternative* and thus we have for any i ,

$$\sum_p n_{ip} \cos \theta_{ip} = 0 \quad (4)$$

as a restrictive condition on the configuration.

Put into words this means that an atom in the lattice must lie at the center of gravity of each of the concentric surrounding shells of atoms. Most, if not all, of the known crystalline elements obey this condition, so that it cannot be called highly restrictive.

Having disposed of the terms involving dx we now develop dU_i in terms of dx .² Referring again to Fig. 6, it will be seen that $dU_i = \frac{1}{2}(W_i'' \sum_p n_{ip} \cos^2 \theta_{ip}) dx^2$, in which the coefficients of W_i'' are always positive. But W_i'' may be either positive or negative, so we have no *a priori* knowledge of whether $\sum dU_i$ is positive or negative. If negative the lattice is in unstable equilibrium. Since we know, however, that actual lattices are actually in stable equilibrium we have the strongest reasons for believing that

$$\sum_i \left(W_i'' \sum_p n_{ip} \cos^2 \theta_{ip} \right) > 0 \quad (5)$$

and we can hereafter use this series for comparison.

2. *Equilibrium against uniform extension in one direction.* We now assume that the whole lattice is uniformly stretched in the X -direction at the same time not permitting it to contract laterally. Let the amount of stretch per unit length be ϵ . Referring again to Fig. 6, we see that bond ip is stretched an amount $\epsilon k_i r_0 \cos^2 \theta_{ip}$. Hence

$$dU_i = k_i W_i' \epsilon r_0 \sum_p n_{ip} \cos^2 \theta_{ip}$$

where θ_{ip} is now confined to values between $-\pi/2$ and $+\pi/2$. If equilibrium exists

$$\sum_i k_i W_i' \sum_p n_{ip} \cos^2 \theta_{ip} = 0.$$

Comparing the above expression with Eq. (2) as before, it is plain that we have the same two alternatives; but since the coefficients of W_i' in the above expression are definitely positive, each one must be the same multiple of the corresponding coefficient in Eq. (2), i.e.

$$\sum_p n_{ip} \cos^2 \theta_{ip} = a n_i \quad (6)$$

where a is the same constant for every different value of i , but not the same for different directions of the axis of elongation.

This result may be put into more familiar terms by saying that the planar moment of inertia of every shell of atoms with respect to a given YZ plane is

* For $\sum_p n_{ip} \cos \theta_{ip} \leq n_i$, while n_i becomes a smaller and smaller fraction of $k_i n_i$.

the same fraction of $k_i^2 r_0^2 n_i$ for that shell. In particular it will be noticed as a result of familiar properties of moments of inertia, that the principal axes of inertia have the same directions for all shells, and the principal moments of inertia are in the same proportion. This constitutes a very severe restriction on the pattern of the lattice.

The terms in ϵ^2 are now to be evaluated. By a similar reasoning to that employed in the previous paragraphs, we find

$$dU_i = \frac{1}{2} W_i'' k_i^2 \left(\sum_p n_{ip} \cos^4 \theta_{ip} \right) \epsilon^2 r_0^2$$

or

$$dU = \frac{1}{2} \epsilon^2 r_0^2 \sum_i k_i^2 W_i'' \sum_p n_{ip} \cos^4 \theta_{ip}$$

and since we have experimental evidence that crystals are in stable equilibrium against just such an extension as this, we are justified in concluding that

$$\sum_i k_i^2 W_i'' \sum_p n_{ip} \cos^4 \theta_{ip} > 0. \quad (7)$$

The series in Eq. (7) is proportional to the elastic constant c_{11} for the X -axis we have selected.

3. *Equilibrium against shear.* Imagine the lattice distorted parallel to the XY plane, the displacements being given by $dy = \epsilon x$, $dx = 0$, $dz = 0$. This is a simple shearing distortion. The first order terms in the energy-change are of the type

$$dU_i = \epsilon r_0 k_i W_i' \sum_p \cos \theta_{ip} \sin \theta_{ip} \sum_q \cos \phi_q$$

where ϕ_q is the angle between the XY plane and the plane through the X -axis which contains the atom in question, and where the summation with respect to q means summation over the atoms lying in the circle of intersection of the plane p and the shell i . This expression may be rewritten:

$$dU_i = \frac{\epsilon W_i'}{k_i r_0} \sum_r x_r y_r$$

where the summation is over the atoms of the i th shell. For all the shells:

$$dU = \epsilon r_0 \sum_i k_i W_i' \sum_r \frac{x_r y_r}{k_i^2 r_0^2}$$

and if this latter expression equals zero we have:

$$\sum_i k_i W_i' \sum_r \frac{x_r y_r}{k_i^2 r_0^2} = 0.$$

Comparing this equation with Eq. (2) as before, we find the two only compatible if

$$\sum_r x_r y_r = f n_i k_i^2 r_0^2 \quad (8)$$

where f is the same constant for each value of i , but varies with the orientation of the coordinate frame. It turns out that Eq. (8) is a consequence of Eq. (6), as a simple calculation will demonstrate. Thus, equilibrium against shear introduces no restriction on the lattice geometry beyond what was already imposed by the equilibrium against unidirectional elongation. (This might have been directly inferred from the theory of elasticity).

The expression for dU in terms of ϵ^2 must be greater than zero if the equilibrium against shear is stable. The corresponding inequality is:

$$\sum_i k_i^2 W_i'' \sum_p \sin^2 \theta_{ip} \cos^2 \theta_{ip} \sum_q \cos^2 \phi_q > 0. \quad (9)$$

The series in Eq. (9) is proportional to the elastic constant c_{66} for the axes selected.

4. *Equilibrium against displacement of a large portion of the lattice.* The principal object in deriving the equations of the preceding paragraphs was not to prove that crystals can exist, for we know this from observation, but to obtain certain series in W_i' and W_i'' of which the sums are known to vanish, or be positive respectively, and which can be used for comparison with other series in W_i' and W_i'' of which the behavior is not known from observation.

We now draw another picture of our lattice, Fig. 7, in which we once more show all the atoms lying on a series of equidistant planes, each plane

Fig. 7.

containing an equal number of atoms. (For some lattices the planes may not be equidistant, or equally densely packed, but there will always be a repetition of the same distances in the same order, and the argument is but little affected). The X -axis is an arbitrary line in space as before. Though the transverse planes may be very close together and contain each but a few atoms, nevertheless the lattice can always be resolved into such a series of planes with finite separation and perpendicular to an arbitrary axis. The distance between planes is αr_0 .

Now we elect to remove the portion of the lattice lying to the right of 0 by a distance dx from the portion to the left. In so doing we elongate every bond crossing the gap dx by an amount $dx \cos \theta_{ip}$.

We must also notice that if $k_i \cos \theta_{ip} = \alpha$, only the atoms lying in the plane through 0 have their bonds affected. But if $k_i \cos \theta_{ip} = 2\alpha$, then the plane through 0 and also its neighbor on the left contain atoms whose bonds are lengthened; and in fact if $k_i \cos \theta_{ip} = p\alpha$ there are p planes to the left of 0, and including 0, containing atoms whose i th bonds are lengthened by the operation. So if there are N atoms in each plane

$$dU_i = NW_i' dx \sum_p n_{ip} p \cos \theta_{ip}$$

But $p = k_i \cos \theta_{ip} / \alpha$ hence

$$dU_i = \frac{Nk_i W_i' dx}{\alpha} \sum_p n_{ip} \cos^2 \theta_{ip}$$

and

$$dU = (Ndx/\alpha) \sum_i W_i' k_i \sum_p n_{ip} \cos^2 \theta_{ip} \quad (10)$$

where θ_{ip} takes on values between $-\pi/2$ and $+\pi/2$.

But Eq. (6) told us that $\sum_i [W_i' k_i \sum_p n_{ip} \cos^2 \theta_{ip}] = 0$. Hence in Eq. (10) $dU = 0$. Hence the lattice is in equilibrium against the assumed displacement.

We now develop dU in terms of dx^2 as follows:

$$\begin{aligned} dU_i &= \frac{1}{2} N dx^2 W_i'' \sum_p n_{ip} p \cos^2 \theta_{ip} \\ &= \frac{1}{2} \frac{N dx^2 W_i'' k_i}{\alpha} \sum_p n_{ip} \cos^3 \theta_{ip} \end{aligned}$$

whence

$$dU = (N dx^2 / 2\alpha) \sum_i k_i W_i'' \sum_p n_{ip} \cos^3 \theta_{ip} \quad (11)$$

The question whether the equilibrium we have been discussing is stable depends on whether the series in Eq. (11) is positive.

To settle this matter we shall require the series of Eq. (7) for purposes of comparison. Let us use the letter S for the latter series and the letter S' for the series of Eq. (11). If we now refer to Fig. 2 we see that for the first few terms W_i'' is positive, and for all the remainder out to infinity W_i'' is negative. Let us say that W_μ'' is the last positive term. Then we may write $S = S_A - S_B$ where S_A is a terminating series ending with W_μ'' , and S_B is an infinite series of positive terms starting with $-W_{\mu+1}''$. The fact that $S > 0$ implies that $S_A > S_B$. Similarly we divide S' into two parts S_A' and S_B' the division being at the same term as for S . Let the i term of S be S_i and the i term of S' be S_i' . Then

$$\begin{aligned} \frac{S_i}{S_i'} &= \frac{k_i^2 W_i'' \sum_p n_{ip} \cos^4 \theta_{ip}}{k_i W_i'' \sum_p n_{ip} \cos^3 \theta_{ip}} \\ &= \alpha \cdot \frac{k_i W_i'' \sum_p p n_{ip} \cos^3 \theta_{ip}}{k_i W_i'' \sum_p n_{ip} \cos^3 \theta_{ip}} \end{aligned}$$

Let $S_i/S'_i = t_i$. Evidently $\alpha < t_i < \alpha q_i$ where q_i is the largest integer in k_i/α , i.e., the largest value of p . Also $t_i < t_{i+1}$.*

We may now write the two series as follows:

$$S = S_A - S_B = \sum_1^{\mu} t_i S'_i - \sum_{\mu+1}^{\infty} t_i S'_i$$

$$S' = S_A' - S_B' = \sum_1^{\mu} S'_i - \sum_{\mu+1}^{\infty} S'_i.$$

Then

$$\alpha < S_A/S_A' < t_{\mu} < \alpha q_{\mu} \leq \alpha q_{\mu+1} < S_B/S_B'.$$

or

$$S_A/S_A' < S_B/S_B'.$$

But

$$S_A > S_B$$

hence

$$S_B/S_A' < S_B/S_B'$$

or

$$S_A' - S_B' > 0.$$

The expression in Eq. (11) is therefore positive, and the equilibrium is stable. In other words, any displacement of a portion of the perfect lattice directly away from another portion sets up a restoring force. If the crystal does not extend to infinity to right and left, the effect will only be to make S_B and S_B' terminating series, and the inequalities will be even more pronounced. It only remains to carry through a similar argument with respect to a lateral displacement of one portion of the lattice relative to the other. It turns out that, using a similar notation and procedure to that which preceded,

$$S = \sum_i k_i^2 W_i'' \sum_p \cos^2 \theta_{ip} \sin^2 \theta_{ip} \sum_q \cos^2 \phi_q \quad (\text{Eq. 9})$$

$$= \alpha \sum_i k_i W_i'' \sum_p p \cos \theta_{ip} \sin^2 \theta_{ip} \sum_q \cos^2 \phi_q$$

and

$$S' = \sum_i k_i W_i'' \sum_p \cos \theta_{ip} \sin^2 \theta_{ip} \sum_q \cos^2 \phi_q.$$

From which, as before, we find that $dU > 0$ and the equilibrium is stable with respect to this displacement too.

POSSIBLE CLASSES OF SYMMETRY IN HOMOPOLAR CRYSTALS

In this section we shall discuss rather briefly the consequences of Eqs. (4) and (6), so far as they affect the symmetry properties of homopolar lattices as defined in the opening paragraph.

The meaning of Eq. (4) is that any atom in the lattice must lie at the center of gravity of any group of atoms which are situated on the surface of a

* For large values of k , t approaches $(4/5)k$; there may be isolated values of i for which $t_i > t_{i+1}$ but these are very rare. It is impossible to imagine a W function for which this slight departure from rigor would invalidate the general conclusion.

sphere with the atom in question at its center. It is plain that the atoms of such a group must display at least all the elements of symmetry of the crystal as a whole. (They may display additional elements of symmetry, but here we are concerned with minimum requirements.)

The elements of symmetry, so far as they affect our present argument, are: (1) a center of symmetry; (2) an axis of symmetry, either digonal, trigonal, tetragonal or hexagonal; (3) a plane of symmetry. The properties of these as they affect the center of mass are as follows:

1. The center of gravity coincides with a center of symmetry if one exists.
2. Any axis of symmetry contains the center of gravity.
3. Any plane of symmetry contains the center of gravity.

Since all elements of symmetry of points on a sphere contain the center of the sphere, it is sufficient that the elements of symmetry shall determine a point, to make that point the center of gravity. This then may be accomplished in the following ways:

- (1) A center of symmetry.
- (2) Two axes of symmetry of any order.
- (3) An axis of symmetry and a plane of symmetry which does not contain the axis.
- (4) Three non-collinear planes of symmetry.

Any class of symmetry, then, which displays at least one of the four combinations of symmetry elements listed above, fulfills the requirements of

† Table copied from Wykoff: "The Structure of Crystals", N. Y. 1924.

Eq. (4). In Table I are listed the 32 recognized classes of crystal symmetry. Those classes which obey Eq. (4) are designated with asterisks. Of the 32

classes, 21 obey this condition. All the known space lattices of crystal elements fall into the 21 classes with the possible exception of graphite, of which the lattice is still the subject of discussion.

We still have to discuss the consequences of Eq. (6), which imposes a restriction far more severe than Eq. (4).

Eq. (6) demands that the principal axes of inertia of each sphere of atoms concentric with a selected atom shall have the same directions (this also follows from symmetry considerations) and that the principal planar moments of inertia shall be in the same proportion. So far as the writer can determine, this condition is satisfied by the five classes of the cubic system and none other. The hexagonal close-packed arrangement may be said to satisfy the condition 'approximately', i.e. the first departure is in the shell $i=3$, and involves the transfer of two atoms from a shell containing twelve, to a shell of about 6 percent smaller radius. Just what meaning can be attached to this 'approximate' fulfilment of such a condition is not clear. It may mean that this small departure from equilibrium can be balanced by a minute polar force-field superposed on the central force-field which we have postulated in the first paragraph of the Fundamental Statements above.

It may finally be remarked that if Eq. (2) has a solution r_0 for a particular lattice type, and if this lattice type satisfies Eqs. (2) and (4), and if $\sum n_i W_i$ is smaller for this configuration than for any of the other configurations satisfying Eqs. (1), (2) and (4), then the inequalities expressed by Eqs. (5) and (7) show that no lattice obtained by a homogeneous deformation of the given lattice can satisfy the given conditions. Moreover, since the validity of these inequalities is only increased by leaving out terms beyond the first few terms in the summations, all departures from complete geometrical perfection in the interior of a homopolar crystal are unstable.

At points near the surface of a crystal, particularly for points nearer to the surface layer than the distance at which $W_i''=0$, the above statement is not true; the writer hopes to make those surface conditions the subject of a future paper.

MOSAIC STRUCTURES

The displacement of one portion of a crystal *en bloc* relative to the other portion may be said to be the purest type of inhomogeneous deformation. From the two cases of this kind which we have considered above, in conjunction with the postulated stability against homogeneous deformation, it is possible to show that any conceivable picture of inhomogeneous deformation leads to an increase of energy in the second order terms of the displacements. Among others, it is possible to show that the equilibrium is stable against a uniform or non-uniform contraction of a single lattice plane.

Two types of variation from perfect symmetry are conceivable mosaic structures. The first is obtained by some sort of inhomogeneous deformation of an originally perfect lattice. Our conclusions given above show that any such configuration involves a greater energy than the original.

The second is obtained by some such inhomogeneous deformation forming gaps in the lattice into which additional atoms are inserted. To show that this results in a preferred configuration it is necessary not merely to show (a) that the new atom has a negative potential energy greater than the positive energy created by the deformation, but also (b) that the net decrease in energy thereby effected is greater than what would result from adding one more atom in a normal way to the structure of the perfect lattice. Zwicky⁶ in replying to the author's⁴ criticism his general thermodynamic argument for all crystals, recapitulates his calculations for an ionic lattice (rock salt), and establishes the condition (a) above; but he does not show that condition (b) is satisfied as well.

Evjen² has calculated the case of inhomogeneous deformation of a rock-salt lattice and finds as we do here for a homopolar lattice, that the energy terms in the second powers of the displacements are positive. He does, however, find that when terms of the third and fourth powers are included, it is possible to find a secondary minimum in the energy which may be lower than the original minimum.

In concluding the author wishes to express to Professors K. F. Herzfeld and F. D. Murnaghan his appreciation of their comments on certain portions of this paper.

THE INFLUENCE OF TEMPERATURE ON POLARIZATION CAPACITY AND RESISTANCE

BY E. E. ZIMMERMAN

EDGEWOOD ARSENAL, EDGEWOOD, MARYLAND

(Received January 16, 1930)

ABSTRACT

The temperature coefficients of polarization capacity and resistance have been determined for gold and plain platinum electrodes in 0.63, 1.50 and 2.42 N solutions of sulphuric acid and also at different frequencies for 1.46 N concentration. To reduce the electrodes to a condition representing minimum capacity, a method of thermal treatment was employed and found quite effective. Values of the angle of phase difference have been computed for the various conditions under which measurements were made.

During the process of reducing the electrodes to a condition representing minimum capacity, the value of polarization capacity decreased to about one-half the original value and the resistance increased to a few times the original value. The angle of phase difference increased 15 or 20 degrees. After the electrodes were conditioned, consistent and reproducible values of capacity and resistance could be obtained.

The temperature coefficient of capacity is about twice as great with platinum as with gold electrodes and is apparently independent of concentration. Phase difference changes only slightly with temperature, but increases with concentration. The absolute values of the slopes of the curves, capacity versus temperature and resistance versus temperature, decrease with increasing frequency. The temperature coefficient of capacity, however, increases with frequency for platinum electrodes and decreases in the case with gold electrodes.

THERE has been a limited amount of investigation of the effects on polarization capacity and polarization resistance caused by changes in temperature. Sheldon, Leitch and Shaw¹ determined the temperature coefficient of capacity for cells consisting of $\text{Pt}|\text{H}_2\text{SO}_4|\text{Pt}$ and $\text{Hg}|\text{H}_2\text{SO}_4|\text{Pt}$. Schönherr² studied the influence of temperature on the reduction of the electrodes to a condition corresponding to minimum capacity. The work herein described was an investigation to determine the nature and magnitude of changes in polarization capacity and resistance as influenced by changes in temperature, under various conditions with respect to the concentration of the electrolyte, the frequency of the applied voltage and the material and condition of the electrodes.

APPARATUS AND EXPERIMENTAL PROCEDURE

Measurements were made by means of the Wheatstone bridge and auxiliary apparatus, diagrammatically represented in Fig. 1. The low-power vacuum tube oscillator which had a frequency range from 600 to 4000

¹ Sheldon, Leitch and Shaw, *Phys. Rev.* (1) 2, 401 (1895).

² Schönherr, *Ann. d. Physik u. Chemie* 6, 116 (1901).

cycles per second was loosely coupled to the bridge by means of a step-down transformer in order to maintain the voltage across the polarization cell at or below the value corresponding to minimum or initial-capacity. Minimum or initial-capacity is that value of polarization capacity characteristic of the cell when the applied voltage is sufficiently low that further decrease in voltage does not result in any appreciable decrease in the value of polarization capacity. With respect to variations in capacity as influenced by variations in voltage, Wien³ found that the polarization capacity was constant at the minimum value if the voltage across the cell was 0.05 or less. Wolff⁴ found the capacity nearly constant for voltages less than 0.1 volt. In the present work, in order to ascertain whether or not variations in applied voltage were influencing the measurements, the voltage across the polarization cell was measured by means of a vacuum tube voltmeter and was found to be less than the critical value. Also, resistance was inserted in the leads to the bridge without decreasing the measured value of capacity. All values of polarization capacity recorded in this paper are, therefore, thought to be

Fig. 1. Bridge and auxiliary apparatus.

minimum values insofar as the influence of the voltage applied to the cell is concerned.

The resistances, R_1 and R_2 , in the ratio arms of the bridge were maintained equal in order to minimize the effects of distributed capacity and inductance although with the type of bridge used and at the comparatively low values of frequency, effects of distributed capacity and inductance were negligible. The condenser, C_1 , was a fixed condenser and served to prevent any direct current through the cell.

Fig. 2 is a diagram of the polarization cell. The cell consisted of a container in the form of a test tube, with a pair of similar electrodes mounted by inserting through the perforated stopper the glass tubes into which the wire electrodes were sealed. The thermometer was similarly mounted with the center of the bulb in the same horizontal plane as the faces of the electrodes, the thermometer and electrodes being securely fastened together so that the faces of the electrodes were coplanar and about 3 mm apart. The end of any glass tube containing an electrode was ground transversely to the length so that the exposed circular cross-section of the wire electrode was

³ Wien, Ann. d. Physik u. Chemie 58, 37 (1896).

⁴ Wolff, Phys. Rev. 27, 755 (1926).

flush with the end of the tube. Gold and plain platinum electrodes were used, the gold having a diameter of 2 mm and the platinum a diameter of 0.623 mm. Under the conditions of the experiment, the capacity of polarization cells with electrodes as described was within the range from 0.03 to 0.7 microfarads and the corresponding range of polarization resistance was from 4000 to 500 ohms. For any particular test the electrolyte was an aqueous solution of sulphuric acid of desired concentration, which had been heated to free it of absorbed gases. The temperature of the cell was controlled by immersing it in an oil or water bath, the temperature of which could be controlled at will.

Fig. 2. Polarization cell. *E*, electrode. *T*, bulb of thermometer.

Data were obtained for any one set of conditions by making a series of measurements as the temperature was increased through a range from 0°C to a maximum of 90 or 95°C and then decreased through the same range.

THE EFFECT OF THERMAL TREATMENT ON STABILIZATION OF THE ELECTRODES

As have other experimenters,⁵ the writer found that cells having freshly surfaced electrodes do not give consistent and reproducible values of capacity and resistance. Incidentally, in attempting to duplicate results for rising and falling temperatures of a cell with freshly surfaced⁶ electrodes, it was found that the effect of any so-called temperature run such as that described above was to decrease considerably the values of capacity and increase the values of resistance. The value of the capacity at 0°C after the cell had been taken through the range of temperatures was reduced to a value which was from 40 to 60 percent of the original value at that temperature on starting the run. More marked changes took place in the resistance, the final value of which might be as much as four times greater after the conditioning runs. After

⁵ Gordon, Göttingen Diss. 72 (1896-97); Orlich, Diss., Berlin (1896); Wolff, reference 4.

⁶ The electrodes were surfaced by filing with a fine-grained file.

two or three such runs with a cell, values of capacity and of resistance obtained with falling temperature were in agreement with those obtained with rising temperature. Schönherr,⁷ also, found by increasing the temperature of the cell through a considerable range and then decreasing it through the same range that the final value of capacity was much less than the original value.

The manner in which polarization capacity and resistance change for freshly surfaced platinum electrodes when the cell is subjected to a series of runs is shown by the curves of Fig. 3. Curve *A* shows the relation between capacity and temperature for the initial run and curve *B* shows the relation

Fig. 3. Capacity-temperature and resistance-temperature curves for platinum electrodes while in the process of being conditioned. For explanation of curves, see text. Values of capacity are in microfarads per sq cm for one electrode and the plotted values of resistance represent total resistance of the cell. To obtain resistance per sq cm for one electrode, the values as plotted should be multiplied by 0.0015. Open circles, without and with crosses, represent values of capacity for increasing and decreasing temperature, respectively, while filled-in circles represent values of resistance, circles with projections being values obtained with decreasing temperature. For all curves, the concentration was normal and the frequency was 1020 cycles per second.

for the third run, the second having given results nearly the same as the third. The corresponding curves showing the development of polarization resistance⁸ are *A'* and *B'*, respectively. It may be noted in curve *B* (capacity)

⁷ Schönherr, reference 2.

⁸ Values of resistance are in all cases the measured values of the total resistance of the polarization cell without deducting for the resistance of the electrolyte which was assumed negligibly small in comparison with the resistance of polarization. A test of the validity of this assumption was made by varying the spacing between the electrodes and noting the effect on resistance. When the spacing was increased to 16 times the original value, the resistance

and in curve B' (resistance) that the agreement between the values of capacity and of resistance for rising temperature and the corresponding values for falling temperature is reasonably good. This same fact is also well emphasized in the curves of Fig. 4, in nearly all of which the values obtained with rising temperature are in very good agreement with those obtained with falling temperature. The one prominent exception in the curves of Fig. 4 is in the case of curves C (capacity-temperature for 0.63 N solution, with plain platinum electrodes) and C' (the corresponding curve for resistance). The lack of agreement in this case is due to the fact that these curves represent the first run of the series with the platinum electrodes and there had been only one run made to condition the electrodes previous to taking the data for these curves. The one run was not sufficient fully to condition the electrodes. In fact, in curves B and B' which are plotted from measurements made during a run following that for curves C and C' , there is still lack of complete agreement between the rising and falling-temperature branches of the curves.

When cells with gold electrodes were treated similarly, the effect was similar, excepting that the gold electrodes were more readily conditioned and did not require as many conditioning runs as did the platinum electrodes.

Success in duplication of results in making measurements of polarization capacity and resistance was possible only when the electrodes were fully conditioned. The writer found the method of thermal treatment as described above to be quite effective in accomplishing this and it is, moreover, a method which requires much less time than that of leaving the electrodes in the electrolyte to age for several days. Just what the condition of the electrode is when it has minimum capacity for a given set of conditions, is not definitely known. It doubtless represents a certain condition with respect to absorbed gas and also with respect to the condition of the surface. As have other experimenters, the writer observed that the electrodes undergo a change in color as they become conditioned, changing from a bright to a dull color. It was also observed that the electrodes could be conditioned in an electrolyte of given concentration and then be used in an electrolyte of different concentration and yet have capacity according to the second concentration.

In curves A and A' , Fig. 3, on the rising-temperature branches of the curves, attention is called to the fact that at a temperature of about 31° , the capacity underwent a rather sudden decrease and the resistance a sudden increase. The cause for these changes was a drop of about 1° in the temperature of the cell at this point after which, although the temperature was

increased only 3.5 percent. Also, the platinum electrodes which were used during the experimental work were finally platinized and the total resistance was determined. The value thus determined, when corrected for concentration, was not in any case more than 5 percent of the total resistance of the cell with plain platinum electrodes. Since part of the resistance of the cell as measured with platinized electrodes was resistance of polarization for platinized platinum, the value of the resistance of the electrolyte thus determined was somewhat too large. Consequently, 5 percent is a liberal estimate of the outside limit of the approximation.

again brought to its former value, the values of capacity and of resistance had undergone the changes noted. Later, in order to investigate this effect further, the electrodes were again freshly surfaced and the data represented in curves C and C' were obtained. In taking the data for these curves, the temperature was purposely permitted to fall 1 or 2 degrees at three different points on the ascending parts of the curves. The curves show that apparently the reversal of the temperature gradient with reference to the electrode and the electrolyte is effective in decreasing the capacity and increasing the resistance and also that a change in capacity is accompanied by a corresponding and closely related change in resistance.

During the conditioning process in case of the cell with platinum electrodes the phase difference, i.e., $\tan^{-1}\omega RC$, where ω is $2\pi \times$ frequency, R is polarization resistance and C is polarization capacity, increased from 27° to 40° and in case of the cell with gold electrodes the phase difference increased from 12° to 35° . The initial low value of phase difference in the latter case is probably due to the fact that the gold electrodes had previously been heated to the melting point, while in the case with the platinum electrodes, the electrodes had been freshly surfaced by filing, only. The electrode, then, having the property of polarization capacity, may be regarded as becoming a less perfect condenser as the electrode becomes conditioned or as it acquires the condition corresponding to minimum capacity.

The writer has chosen in this paper to regard polarization capacity and the resistance associated with it as being equivalent to a pure capacity and a pure resistance in series. Successful attempts were made, however, to balance the bridge both with a resistance in series with a mica condenser in the arm of the bridge opposed to the polarization cell, and also with a resistance in parallel with the standard condenser. The results were as follows:

Measured values of capacity and resistance when the cell was balanced by a capacity and resistance in series were, respectively,

$$0.0515 \mu f \text{ and } 2840 \text{ ohms.}$$

When C_m and R_m , signifying the corresponding values for the multiple relation, are computed from the above values,

$$C_m = \frac{C_s}{1 + \omega^2 C_s^2 R_s^2} = 0.0274 \mu f$$

and

$$R_m = R_s \left(1 + \frac{1}{\omega^2 C_s^2 R_s^2} \right) = 6070 \text{ ohms.}$$

The values of C_m and R_m as measured directly by means of the bridge were, respectively, $0.0292 \mu f$ and 5920 ohms, in reasonably good agreement with the computed values. The balance or null point was quite distinct in both cases.

TEMPERATURE COEFFICIENT AND CONCENTRATION OF THE ELECTROLYTE

With gold and plain platinum electrodes, conditioned according to the method described above, data were taken for different concentrations of the electrolyte as the temperature was varied over the complete range. The data so obtained are plotted in the curves of Fig. 4, the variation of capacity and

Fig. 4. Curves, capacity-temperature (letters not primed) and resistance-temperature (corresponding, primed letters) for different concentrations of the electrolyte. Curves A, A', D and D' are for 2.42 N concentration; curves B, B', E and E' are for 1.50 N; and curves C, C', F and F' for 0.63 N. The six upper curves are for platinum electrodes and the six lower for gold. For the significance of different kinds of points, see explanation, Fig. 3. The frequency was constant at 1000 cycles per second. All values of capacity are in microfarads per cm² for one electrode, but values of resistance represent the total resistance of the cell. To obtain resistance per cm² for one electrode, the plotted values should be multiplied by 0.0015 for the cases with platinum electrodes and by 0.0174 for the cases with gold electrodes.

the corresponding variation of resistance with temperature for the three different values of concentration being shown for the two kinds of electrodes.

Table I shows results of computations based on the curves of Fig. 4 and the data relating thereto. As is indicated in the table, the temperature coefficient of capacity, defined as

$$(1/C_{18})(dC/dT)_{18},$$

is about twice as much for platinum electrodes as for gold, other conditions being the same. With possibly an exception in the case with platinum electrodes for the 2.42 normal solution, the temperature coefficient for both

TABLE I. *Temperature coefficients of polarization capacity and polarization resistance for different concentrations of the electrolyte.*

Kind of Electrodes Concentration of Electrolyte	Plain Platinum			Gold		
	0.63 N	1.50 N	2.42 N	0.63 N	1.50 N	2.42 N
C_{18}	28.5	44.3	55.3	7.0	10.0	12.6
$(dC/dT)_{18}$	0.29	0.448	0.466	0.0372	0.053	0.067
$(1/C_{18})(dC/dT)_{18}$	0.0101	0.0101	0.0084	0.0053	0.0053	0.0053
R_{18}	4.3*	3.5	2.9	16.7	13.8	12.2
$(dR/dT)_{18}$	-0.045	-0.032	-0.026	-0.067	-0.043	-0.040
$(1/R_{18})(dR/dT)_{18}$	-0.0092*	-0.0089	-0.0089	-0.004	-0.0033	-0.0033

Notes: Values of capacity are in microfarads per cm² for one electrode. Values of resistance are in ohms per cm² of area for one electrode. *N* signifies normal solution (H₂SO₄ in water), i.e., 49 grams of acid per liter of solution. The frequency was constant at 1000 cycles per second.

* This value is somewhat uncertain, due to the fact that the electrodes were not fully conditioned.

Relatively, the values of C_{18} and R_{18} in Table I are accurate to within about 1 percent. Values of $(dC/dT)_{18}$ and $(dR/dT)_{18}$, and, consequently, the values of temperature coefficients, are probably not more accurate than to within 5 percent.

gold and platinum electrodes is independent of concentration for the three values of concentration involved. In other words, C_{18} and $(dC/dT)_{18}$ change in the same manner with respect to changes in concentration.

Also, it may be seen that the values of resistance per unit area of electrode, R_{18} , with platinum are about one-fourth the values for the corresponding concentrations with gold electrodes. On the other hand, values of capacity per unit area are about four times as large with platinum as with gold electrodes for corresponding concentrations. It may be noted from the curves in Fig. 4 that capacity and resistance do not vary linearly with temperature in the cases with platinum electrodes as they do with the gold electrodes.

The value of temperature coefficient of capacity as obtained in this work for platinum electrodes is somewhat less than that computed from the data given by Sheldon, Leitch and Shaw.⁹ The value computed from their data is about 0.02 per degree centigrade when compared to the capacity at a temperature of 18°C.

The degree of variation of the product, capacity of cell times total resistance of cell (regarded as the polarization resistance), is shown in Table II. The corresponding values of the angle of phase difference are also shown in many instances. Although in Table II, the capacity and resistance of the cell were used rather than the values for a single electrode, nevertheless, regarding the capacity and resistance as being in series, the product would not be changed in value in considering the results for a single electrode, for in that case the value of capacity would be double the total capacity of the cell and the value of resistance would be one-half the total resistance of the cell. Since the frequency was constant, Table II also indicates the variations in the tangent of the angle of phase difference for the different conditions represented by the several curves. It may be noted that there is no large

⁹ Sheldon, Leitch and Shaw, reference 1.

variation in the phase difference for any one temperature run. With gold electrodes, the phase difference seems to increase slightly with rising temperature, while with platinum electrodes, for the higher concentrations especially, the phase difference seems to be slightly lower at the higher temperatures. For both kinds of electrodes, the phase difference increases with increase in concentration of the electrolyte.

TABLE II. Variation in product, $C \times R$, with temperature, frequency being constant.

Average	139 (41°00')	157 (44°27')	160 (45°10')	115 (36°00')	138 (40°54')	154 (44°8')

Note: The average values of the angle of phase difference are computed from the average values of ($C \times R$).

In Fig. 5 are curves showing the results of attempted runs after the electrodes had been polarized with oxygen or hydrogen, as indicated in the figure. The electrodes were polarized by connecting the two together and

Fig. 5. Curves, capacity versus temperature, for polarized electrodes. The kind of electrodes and type of polarization are indicated in the figure. In all cases, the concentration was 1.46 N and the frequency was 1000 cycles per sec. Values of capacity are in microfarads per cm² for one electrode.

to the appropriate terminal of a direct current source of potential while a comparatively large third electrode was connected to the other terminal. Excepting in the case of gold polarized with oxygen, the capacity increased

regularly on starting the runs, but at temperatures of about 35° or higher there were sudden and irregular decreases in the value of capacity. Such decreases usually occurred simultaneously with the appearance of gas on the faces of the electrodes. Continuing the runs throughout the range of temperatures, the final values of capacity were much lower, yet still somewhat higher than the minimum values.

TEMPERATURE COEFFICIENT AT DIFFERENT FREQUENCIES

Curves, capacity versus temperature, representing measurements at different frequencies, but with the concentration constant, are very similar to those of Fig. 4. The slopes of the curves decrease considerably with increasing frequency. For platinum the temperature coefficient increases with increasing frequency, while the opposite seems to be true in the case with gold electrodes. The results of such tests are given in Table III. As may be seen from the table, both capacity and resistance decrease markedly with increasing frequency (see under C_{18} and R_{18}).

The variation of polarization capacity and resistance with frequency has been the subject of special investigations by Merritt,¹⁰ Jolliffe,¹¹ and Wolff.¹² The results found in this work for variation of capacity with frequency, although representing a comparatively narrow and somewhat lower range of frequencies, are in general agreement with the results of their investigations.

TABLE III. *Temperature coefficient of capacity at different frequencies.*

Kind of Electrode	Plain Platinum				Gold	
	645.0	1290.0	2581.0	3872.0	645.0	2581.0
C_{18}	60.6	42.4	28.2	21.3	14.7	7.6
$(dC/dT)_{18}$	0.487	0.356	0.250	0.205	0.111	0.048
$(1/C_{18})(dC/dT)_{18}$	0.0080	0.0084	0.0088	0.0096	0.0075	0.0063
R_{18}	4.56	3.18	2.0	1.9	15.5	6.5
$(dR/dT)_{18}$	-0.034	-0.028	-0.015	-0.015	-0.083	-0.029
$(1/R_{18})(dR/dT)_{18}$	-0.0075	-0.0088	-0.0075	-0.0088	-0.0053	-0.0045

Notes: Values of frequency are in cycles per second. Values of capacity are in microfarads per cm² for one electrode. Resistance is in ohms per unit area of electrode. The concentration, 1.46 normal, was the same in all cases.

DISCUSSION

It is very well known that temperature affects in a very important way most electrolytic processes. The temperature coefficient of conductivity of sulphuric acid of normal concentration as given in tables by Kohlrausch and Holborn¹³ is about 0.012 per degree centigrade at a temperature of 22°C. Also, the temperature coefficient of fluidity as based on data from tables is positive with a value of about 0.028 per degree centigrade at 15°C. In consideration of the facts that the temperature coefficients of capacity for platinum and gold in sulphuric acid are not the same and that the variation of

¹² Wolff, reference 4.

¹³ Kohlrausch and Holborn, Leitvermögen der Electrolyte (1916).

capacity with temperature is not linear in the case with platinum, while it is in the case with gold, the temperature coefficients of capacity and resistance are not fully accounted for in variations of conductivity and fluidity with temperature, for if so the coefficients for the two metals would be affected alike.

Knobel and Joy¹⁴ found, with smooth platinum, that increasing the temperature had the effect of decreasing the overvoltage. Overpotential and catalytic activity of metals, according to the work of Rideal,¹⁵ vary inversely, i.e., metals arranged in order of decreasing catalytic activity are also arranged in order of increasing overpotential. Bancroft,¹⁶ also, states that the metals which have a lower overvoltage are those that catalyze the reaction, $2\text{H} \rightarrow \text{H}_2$, while those which have a high overvoltage do not. Among other things, Bancroft also discusses the action of the so-called catalytic poisons in preventing catalysis. Now Wolff¹⁷ has shown that catalytic poisons have the effect of decreasing polarization capacity. It seems quite likely, therefore, that overvoltage, catalytic activity, and polarization capacity are related in an important and probably a very complex way. The decrease in capacity of the electrode as it acquires its stable condition after polishing would mean a corresponding decrease in its catalytic activity. The increase in capacity with temperature would mean an increase in catalytic activity and a reduction in the conditions favorable to overvoltage, as found by Knobel and Joy. It is recognized that in considering polarization capacity in relation to overvoltage one is dealing with much lower values of voltage in the case of polarization capacity, and for so-called minimum capacity, values of voltage which are thought to be strictly reversible.

If polarization capacity and catalytic activity are intimately related, then the results of this paper do not seem to be in full agreement with the work of Bowden and Rideal¹⁸ who found that the specific catalytic activity of the various metals, including platinum, for the electro-deposition of hydrogen suffer only small variations by thermal treatment. Here again, however, the full conditions are not the same, for in this work the capacity was determined by means of a bridge supplied with alternating current and, consequently, not only is the deposition of hydrogen involved, but also the deposition of oxygen and the effect of one on the other after consecutive reversals of the current.

In conclusion, the writer desires to express appreciation of the excellent facilities available at Cornell University, Department of Physics, for doing this work. Thanks are extended to Professor E. Merritt, who approved this problem and under whose direction the work was done, for his interest and many helpful suggestions. The writer is also indebted to Professor C. C. Murdock for his interest in the results of the work and a discussion of their relation to other problems of polarization capacity.

ON THE SOLUTION OF CERTAIN CASES OF THE GENERAL EQUATION OF DIFFUSION

BY R. L. PEEK, JR.
BELL TELEPHONE LABORATORIES, NEW YORK CITY

(Received January 13, 1930)

ABSTRACT

For diffusion in substances for which the conductivity and diffusivity are functions of temperature, the partial differential equation which determines the temperature is non-linear in character. For a certain class of boundary conditions the introduction of an auxiliary function of time and distance reduces this equation to an ordinary differential equation of the second order, in which the temperature and the auxiliary function appear as dependent and independent variables respectively. As this resulting equation can be solved by methods of approximation, the solution to the original equation can be thus obtained.

The conditions under which such an auxiliary function exists are examined and a simple criterion developed by means of which it may be determined whether such a function exists for any particular case. The method is shown to apply to the case of the semi-infinite solid, and the solution of a particular problem of this type (the cooling of a steel ingot) is given. Another case to which the method applies (diffusion in an axially heated cylinder) is considered, and shown to afford a possible method for determining diffusivity as a function of temperature. It is noted that the method developed is available for the solution of problems in the diffusion of matter as well as of those concerned with the diffusion of heat.

THE theory of the diffusion of heat rests upon the assumption that the quantity δQ of heat passing through a plane of area $\delta y \delta z$ in time δt is given by the relation:

$$\frac{\delta Q}{\delta t} = -k \frac{\partial \theta}{\partial x} \delta y \delta z, \quad (1)$$

where $\partial \theta / \partial x$ is the temperature gradient in the direction of the X -axis, and k is the thermal conductivity. When k is taken as a constant, this assumption leads to the well-known differential equation,

$$\frac{\partial \theta}{\partial t} = h^2 \left(\frac{\partial^2 \theta}{\partial x^2} + \frac{\partial^2 \theta}{\partial y^2} + \frac{\partial^2 \theta}{\partial z^2} \right), \quad (2)$$

in which the diffusivity h^2 is the ratio k/cd , c being the specific heat and d the density. If h^2 is taken as a constant, Eq. (2) may be solved for many particular cases by well-known methods.

If k is not a constant, but a function of θ , Eq. (2) no longer applies. The differential equations that then apply for linear and radial flow have been given by many authors; and the general form is easily obtained in a manner analogous to the usual derivation of Eq. (2). The flow into and out of a differential block through the two faces normal to the direction of the X -axis is evidently, from Eq. (1), given by

$$\begin{aligned}\frac{\delta Q}{\delta T_{(x)}} &= -\left(k - \frac{1}{2} \frac{\partial k}{\partial x} \delta x\right) \frac{\partial}{\partial x} \left(\theta - \frac{1}{2} \frac{\partial \theta}{\partial x} \delta x\right) \delta y \delta z \\ &\quad + \left(k + \frac{1}{2} \frac{\partial k}{\partial x} \delta x\right) \frac{\partial}{\partial x} \left(\theta + \frac{1}{2} \frac{\partial \theta}{\partial x} \delta x\right) \delta y \delta z \\ &= \left(k \frac{\partial^2 \theta}{\partial x^2} + \frac{\partial k}{\partial x} \frac{\partial \theta}{\partial x}\right) \delta x \delta y \delta z.\end{aligned}$$

Similar equations apply to the flow into and out of the other two pairs of faces, and the total increment of heat in the differential block is given by the addition of the increments through the three pairs of faces. As the temperature θ is defined by Q/cd , $\delta x \delta y \delta z$, and if k is a function of θ only, there is finally obtained:

$$f(\theta) \frac{\partial \theta}{\partial t} = \left(\frac{\partial^2 \theta}{\partial x^2} + \frac{\partial^2 \theta}{\partial y^2} + \frac{\partial^2 \theta}{\partial z^2}\right) + \frac{1}{k} \frac{dk}{d\theta} \left\{ \left(\frac{\partial \theta}{\partial x}\right)^2 + \left(\frac{\partial \theta}{\partial y}\right)^2 + \left(\frac{\partial \theta}{\partial z}\right)^2 \right\}, \quad (3)$$

where $f(\theta)$ is written for $1/h^2$ or cd/k , as c and d may also be functions of θ . Eq. (3) is the general form of the equation for heat conduction, and reduces to Eq. (2) for the special case where k and h^2 are constants. As is well known, the same equations apply to the diffusion of gases and liquids when θ represents the concentration, k the diffusion constant, and cd the concentration-pressure ratio. The material presented below applies therefore to problems in the diffusion of matter as well as to those dealing with the diffusion of heat.

Due to its non-linear character, Eq. (3) cannot be solved by the methods applicable to Eq. (2). In papers¹ dealing with the experimental determination of k and h^2 will be found discussions of Eq. (3), usually for the case of linear flow [$\partial \theta / \partial y = \partial \theta / \partial z = 0$]. The usual treatment is to employ the solutions of Eq. (2) with approximate corrections applicable to the particular problem. This procedure is facilitated by the use of formal solutions to Eq. (3) such as those obtained by Glage¹ and by Kirchhoff and Hansemann,² among others.

Problems in the interdiffusion of gases have been similarly treated. Boltzmann³ in particular developed formal solutions to Eq. (3) applicable to a number of cases. In the case of the semi-infinite solid, he showed that the solution to Eq. (3) could be expressed formally in terms of the quantity x^2/t only. Advantage has been taken of this relation in the treatment of special cases by Wiedeburg⁴ and Germond.⁵ The procedure given below for the solution of the semi-infinite solid rests upon this same fact: the method will be first discussed in more general terms.

¹ Glage, *Ann. d. Physik* (4) **18**, 904 (1905). This paper gives a critical resume of the classical work in this field.

² Kirchhoff and Hansemann, *Wied. Ann.* **9**, 1 (1880).

³ Boltzmann, *Wien. Ber.* **86**, 63 (1882); *Ann. d. Physik* **53**, 959 (1894).

⁴ Wiedeburg, *Ann. d. Physik* **41**, 675 (1890).

⁵ Germond, *Bull. Am. Math. Soc.* **35**, 460 (1929).

II. The discussion will be limited to the solution of Eq. (3) subject to boundary conditions of the type

$$\begin{aligned}\theta &= c_1 \quad \text{when} \quad F_1(x, y, z, t) = 0, \\ \theta &= c_2 \quad \text{when} \quad F_2(x, y, z, t) = 0.\end{aligned}\quad (4)$$

If θ is so defined, it may be proved that if there exists a function $\Phi(x, y, z, t)$ meeting the following conditions:

$$\begin{aligned}\Phi &= C_1 \quad \text{when} \quad F_1(x, y, z, t) = 0, \\ \Phi &= C_2 \quad \text{when} \quad F_2(x, y, z, t) = 0,\end{aligned}\quad (5)$$

$$\frac{\partial \Phi}{\partial t} = \frac{\left(\frac{\partial \Phi}{\partial x}\right)^2 + \left(\frac{\partial \Phi}{\partial y}\right)^2 + \left(\frac{\partial \Phi}{\partial z}\right)^2}{f_1(\Phi)} = \frac{\frac{\partial^2 \Phi}{\partial x^2} + \frac{\partial^2 \Phi}{\partial y^2} + \frac{\partial^2 \Phi}{\partial z^2}}{f_2(\Phi)}, \quad (6)$$

where $f_1(\Phi)$ and $f_2(\Phi)$ are functions of Φ only, then θ is a function of Φ only, and,

$$(f(\theta) - f_2(\Phi)) \frac{d\theta}{d\Phi} - f_1(\Phi) \frac{d(\log k)}{d\theta} \left(\frac{d\theta}{d\Phi}\right)^2 = f_1(\Phi) \frac{d^2\theta}{d\Phi^2}. \quad (7)$$

For the function θ obtained by integration of Eq. (7) subject to the boundary conditions, $\theta = c_1$ when $\Phi = C_1$, $\theta = c_2$ when $\Phi = C_2$, satisfies Eqs. (4) and also Eq. (3), as the latter, when θ is taken as a function of Φ , reduces to Eq. (7) by virtue of Eqs. (6). Hence θ is the required solution, and the theorem is proved.

In what follows, a function satisfying Eqs. (6) for particular boundary conditions of the type of Eqs. (5) will be termed a resolving function for those boundary conditions.

III. Suppose now that a function θ' has been determined in the above manner for a case of Eq. (3) in which $f(\theta')$ is any function whatever of θ' but in which k is a constant, and the second term to the right of Eq. (3) is therefore zero. Then,

$$\frac{\partial \theta'}{\partial t} = \frac{\frac{\partial^2 \theta'}{\partial x^2} + \frac{\partial^2 \theta'}{\partial y^2} + \frac{\partial^2 \theta'}{\partial z^2}}{f(\theta')}.$$

This is formally identical with the second of Eqs. (6). Substitution for Φ in terms of θ in the first of Eqs. (6) yields:

$$\frac{\partial \theta'}{\partial t} = \frac{\left(\left(\frac{\partial \theta'}{\partial x}\right)^2 + \left(\frac{\partial \theta'}{\partial y}\right)^2 + \left(\frac{\partial \theta'}{\partial z}\right)^2\right) \frac{d\Phi}{d\theta'}}{f_1(\Phi)}.$$

But as Φ is a function of θ' only, $f_1(\Phi)/(d\Phi/d\theta')$ is a function of θ' only. Hence this equation is formally identical with the first of Eqs. (6). There-

fore θ' is itself a resolving function for the particular boundary conditions involved.

It follows that if any resolving function exists for particular boundary conditions, then any solution of Eq. (3) (i.e., θ') when k is constant is, whatever the form of $f(\theta')$, itself a resolving function for these particular boundary conditions.

Applying this theorem to the special case $f(\theta') = 1$, it follows that if any resolving function exists, the solution to this special case is itself a resolving function. But the solutions to this special case are precisely the well-known solutions to Eq. (2) ($k^2 = 1$). Such solutions satisfy the second of Eqs. (6); it is a simple matter to determine by numerical trial if they satisfy the first of these equations. If they do, values of $f_1(\theta')$ vs. θ' may be computed, $f_2(\theta') = 1$, and a solution to Eq. (3) may be obtained by integration of Eq. (7). If they do not, it is proved that no resolving function exists, and the method fails.

The criteria for the use of the method are then that the boundary conditions be of the form of Eqs. (4) and that the known solution θ' for the case $k = \text{constant}$, $f(\theta') = 1$ satisfies both of Eqs. (6).

IV. By actual trial it has been found (in the manner described above) that the method is not applicable to many important cases, such as the diffusion in a slab or cylinder of infinite length when the temperature at the surface is kept constant. It is, however, applicable to the important case of the semi-infinite solid. If in such a solid the initial temperature is θ_0 , while the temperature at the surface $x=0$ is always θ_1 , then Eq. (3) becomes:

$$f(\theta) \frac{\partial \theta}{\partial t} = \frac{\partial^2 \theta}{\partial x^2} + \frac{d(\log k)}{d\theta} \left(\frac{\partial \theta}{\partial x} \right)^2. \quad (8)$$

The problem is then to solve Eq. (8) subject to the conditions,

$$\begin{aligned} \theta &= \theta_0 \quad \text{when} \quad t = 0, \\ \theta &= \theta_1 \quad \text{when} \quad x = 0. \end{aligned} \quad (9)$$

For this problem a resolving function is given by,

$$\Phi = e^{-x/t^{1/2}}. \quad (10)$$

Then from Eqs. (6) and (7), θ is given by integration of

$$\left(\frac{f(\theta) \log \Phi}{2} + 1 \right) \frac{d\theta}{d\Phi} + \Phi \frac{d(\log k)}{d\theta} \left(\frac{d\theta}{d\Phi} \right)^2 + \Phi \frac{d^2 \theta}{d\Phi^2} = 0, \quad (11)$$

subject to the conditions,

$$\begin{aligned} \theta &= \theta_0 \quad \text{when} \quad \Phi = 0, \\ \theta &= \theta_1 \quad \text{when} \quad \Phi = 1. \end{aligned} \quad (12)$$

This integration may be accomplished for any particular case by any of the well-known methods of successive approximations.

This result is of some importance in the solution of physical problems. The most common type of problem in the diffusion of heat involves an initial constant temperature and thereafter the maintenance of another constant temperature on some surface. For all such cases the result for the semi-infinite solid serves as a first approximation, applicable within a high degree of accuracy for an initial time interval sufficiently small. Thus for diffusion in a slab, cylinder, or sphere, the temperature will vary with time and distance from the surface in the same way as for the semi-infinite solid from zero time up to that which the temperature at the center varies by more than the required order of accuracy from its initial value, with the further proviso for the sphere and cylinder that the portion in which the temperature maintains substantially its initial value extend out to a radius beyond which the curvature may be neglected with sufficient accuracy.

V. As an actual example of the method discussed in the preceding section there will be considered the case of the cooling of a large steel ingot, a problem for which the simpler case is discussed by Ingersoll and Zobel, p. 85.⁶ Strictly comparable values of the relations between diffusivity and temperature and between conductivity and temperature were not found in the literature, but data were taken from the Landolt-Börnstein Tables which were thought to be sufficiently representative of a low carbon steel. The diffusivity was taken as that given for Bessemer steel from the data of Kirchhoff and Hansemann,⁷ giving the diffusivity as: $1/f(\theta) = h^2(1 + \beta\theta)$, where $h^2 = 0.1148$ and $\beta = -0.00019$. The conductivity was taken from the mean values given in the Tables⁸ for a 0.64 percent carbon steel, which gave, for the usual approximation of a linear relation: $k = k_0(1 + \alpha\theta)$, where $k_0 = 0.115$ and $\alpha = -0.00046$.

Thus, from Eqs. (11) and (12), the temperature in the block is given by integration of:

$$\frac{d^2\theta}{d\Phi^2} = -\left(\frac{\log \Phi}{2h^2(1+\beta\theta)} + 1\right) \frac{1}{\Phi} \frac{d\theta}{d\Phi} - \frac{\alpha}{1+\alpha\theta} \left(\frac{d\theta}{d\Phi}\right)^2, \quad (13)$$

subject to the boundary conditions which were that $\theta = 800$ when $\Phi = 0$ ($t = 0$), and $\theta = 20$ when $\Phi = 1$ ($x = 0$).

The method of solution employed was that of successive approximations in which the integrations are mechanically obtained by means of an integrator, as described in a paper by Fry.⁹ The work was simplified by taking as a first approximation the well known solution to the problem when h^2 and k are constant, which may be written in terms of Φ as

$$\theta = 800 - \frac{2 \times 780}{\pi^{1/2}} \int_{-(\log \Phi / 2h)}^{\infty} e^{-\lambda^2} d\lambda. \quad (14)$$

In this expression h was taken as having its mean value for the temperature range involved or $(0.1060)^{1/2}$. Due to the discontinuity at $\Phi = 0$ and

⁸ Landolt-Börnstein Tabellen, 5th Ed. p. 1291 (1923).

⁹ T. C. Fry, *Proc. Int. Math. Congress*, Vol. II, p. 405, Toronto (1924).

various associated peculiarities of the equation, some slight modifications in procedure were necessary. Each approximation was made as follows: Given approximations for θ and its first derivative, say θ_n and θ'_n respectively, the corresponding second derivative θ''_n was computed from Eq. (13). This was then integrated to give θ'_{n+1} , the constant of integration being taken such as to give θ'_{n+1} the same value at $\Phi=1$ as that found at this point for θ'_n . In general, this did not make θ'_{n+1} approach zero as Φ approaches zero, a condition which must be satisfied, as is evident from the fact that a function of the type of Eq. (14) is a close approximation to a solution for low values of Φ . Hence θ'_{n+1} was corrected to meet this requirement by taking values of θ proportional to the second term of Eq. (14) up to such a value of Φ as would make this approximation merge into the original curve for θ'_{n+1} without any abrupt change in curvature. The θ'_{n+1} thus corrected

Fig. 1.

was integrated to give θ_{n+1} , the constant of integration being such as to make $\theta_{n+1}=800$ at $\Phi=0$. The difference between 20 and the value of θ_{n+1} at $\Phi=1$, or C , was taken as a correction factor, and a term ΦC added to θ_{n+1} to make it meet both boundary conditions, while the term C was also added to θ'_{n+1} , in accordance with the procedure developed by Fry.⁹ Then θ'_{n+1} was again corrected to make it approach zero as Φ approached zero, by the same method as described above. The values of θ_{n+1} and θ'_{n+1} , thus finally obtained were used to compute θ''_{n+1} and the operation repeated until successive approximations produced no change in θ or θ' .

The solution obtained for the case cited is shown graphically in Fig. 1, in which both θ and θ' are given. The corresponding solution and its first derivative for the case in which the conductivity and diffusivity are constant (the latter taken as $h^2=0.1060$), as given by Eq. (14), are shown in broken lines. It will be seen that the solutions to the two cases differ con-

siderably. To emphasize this difference, Fig. 2 has been prepared, corresponding to Fig. 12, p. 86 of Ingersoll and Zobel,⁶ and giving the rate of cooling ($\partial\theta/\partial t$) at distances of 0.3 cm and 1.0 cm from the face of the block. The broken lines again show the corresponding curves for constant diffusivity and conductivity. It is apparent that consideration of the variation in the conductivity and diffusivity results in a higher maximum rate of cooling than if this variation is neglected.

Fig. 2.

VI. Another case in which the method applies is that of a cylinder of infinite length and radius, initially at one constant temperature, of which the axis is thereafter kept at another constant temperature. If x is the radial distance of any point from the axis, the problem is to solve:

$$f(\theta) \frac{\partial \theta}{\partial t} = \frac{1}{x} \frac{\partial \theta}{\partial x} + \frac{\partial^2 \theta}{\partial x^2} + \frac{d(\log k)}{d\theta} \left(\frac{d\theta}{dx} \right)^2, \quad (15)$$

subject to the conditions,

$$\begin{aligned} \theta &= \theta_0 \quad \text{when} \quad t=0, \\ \theta &= \theta_1 \quad \text{when} \quad x=0. \end{aligned} \quad (16)$$

For this case also the Φ of Eq. (10) is a resolving function. From Eqs. (6) and (7), θ is given by integration of

$$\left(\frac{f(\theta) \log \Phi}{2} + \frac{1}{\log \Phi} + 1 \right) \frac{d\theta}{d\Phi} + \Phi \frac{d(\log k)}{d\theta} \left(\frac{\partial \theta}{\partial \Phi} \right)^2 + \Phi \frac{d^2 \theta}{d\Phi^2} = 0. \quad (17)$$

subject to the conditions of Eqs. (12).

Brown and Furnas¹⁰ have discussed the determination of a variable diffusivity by the graphical integration of Eq. (15) for numerical values of the differential terms of this equation in the case of a centrally heated cylinder.

¹⁰ Brown and Furnas, Trans. Am. Inst. Chem. Engineers 18, 295 (1926).

The above development suggests a procedure in which the measurements and computation would be simpler, though the experimental conditions would be more difficult to obtain, as to maintain a constant temperature along the axis would require some method of adjusting the current in the central heating coil in such a way as to fulfill this condition. It would also be necessary to limit the measurements to a temperature range such that the surface never varied appreciably from its initial value. If these conditions are fulfilled Eq. (17) applies, and (assuming k known as a function of θ^*), it is only necessary to take readings from one thermocouple (one value of x), as θ is a function of Φ only, and any value of Φ will be obtained at any x for some value of t . Expressing the values of t in terms of Φ , values of θ vs. Φ are experimentally obtained. Then by graphical differentiation, or numerically by successive differences, values of $d\theta/d\Phi$ and $d^2\theta/d\Phi^2$ may be obtained, and Eq. (17) solved for $f(\theta)$, the reciprocal diffusivity, as a function of temperature.

VII. The development discussed above permits the reduction of the general differential equation of diffusion to a single ordinary differential equation of the second order, which can be readily solved by methods of approximation. The only particular case of major importance to which the method applies is that of the semi-infinite solid, which affords, however, a good approximation to a solution for many other cases within limited ranges of the co-ordinates of time and distance. The form of the differential equation resulting when the method applies is such as to make the solution by the method of successive approximations preferable, and for this graphical methods are more convenient than numerical.

As is apparent in the example given above, solutions obtained by this method when the variations in conductivity and diffusivity are allowed for may differ considerably from those obtained on the assumption that these quantities are constant. Such differences may be particularly apparent in the values obtained for rates of cooling or of temperature gradients, as the example again indicates, and it is in the evaluation of these quantities that most accurate determinations are desirable (*e.g.*, in the casting of metals and glass). It must, however, be admitted that conditions in technical operations seldom approach those of the mathematically ideal problem sufficiently to make such accuracy in calculation significant, and the developments discussed above are more likely to be of practical importance in problems concerned with material diffusion than in those involving heat.

Acknowledgment is due Dr. T. C. Fry of these Laboratories for much helpful criticism of the work reported in this paper.

* This relation would be previously determined by measurements for the steady state, as discussed by Brown and Furnas (reference 10).

LETTERS TO THE EDITOR

Prompt publication of brief reports of important discoveries in physics may be secured by addressing them to this department. Closing dates for this department are, for the first issue of the month, the twenty-eighth of the preceding month; for the second issue, the thirteenth of the month. The Board of Editors does not hold itself responsible for the opinions expressed by the correspondents.

On the Theory of Electrons and Protons

In a recent paper,¹ Dirac has suggested that the reason why the transitions of an electron to states of negative energy, which are predicted by his theory of the electron, do not in fact occur is that nearly all of the states of negative energy are already occupied. Dirac has further shown that the unoccupied states of negative energy have many of the properties of protons; that, for instance, they may be represented by wave functions which would be taken to correspond to a particle of positive charge and positive mass. He has further shown that the mass associated with these gaps is not necessarily the same as that of the electron, and he has suggested the assumption that the gaps are protons. In order to account for the fact that the divergence of the electric field is not, in spite of the infinite electron density, everywhere infinite, Dirac further assumes that only the departures from the normal state in which all negative states are filled are to be counted in computing the charge density for Maxwell's fourth equation

$$\text{div } E = -4\pi\rho. \quad (1)$$

Finally, Dirac is able to account for the validity of the Thomson formula for the scattering of soft light by a free electron, in spite of the fact that the derivation of this formula on his theory of the electron—a derivation which makes explicit use of the transitions to states of negative energy which are now forbidden, is invalid. According to Dirac, the scattering takes place by a double electron jump, in which a negative² electron jumps up to some state of positive energy,

and the original positive electron falls down into the gap left.

There are several grave difficulties which arise when one tries to maintain the suggestion that the protons are the gaps of negative energy, and that there are no distinctive particles of positive charge. In the first place, we can easily see that Dirac's theory requires an infinite density of positive electricity; and since we should expect the de Broglie waves of this charge to be quantized, we should expect some corpuscular properties for the positive charges. The reason why the theory requires an infinite positive charge is this: If the explanation of the scattering of an electron is to be tenable, a negative electron must interact with the electromagnetic field in the way predicted by Dirac's theory of the electron; for otherwise the scheme proposed would not give the Thomson formula. But this means that there must be a term involving the current and charge vector of the negative electrons in the total energy momentum tensor for matter and radiation. Thus by (1), the divergence of the electric field will be everywhere infinite unless there is an infinite density of positive electricity to compensate the negative electrons.

A further difficulty appears when we try to compute the scattering of soft light by a proton. This difficulty is not unconnected with the difference in mass between the electron and proton, and makes it seem improbable that this difference can be explained on the basis suggested by Dirac. For the scattering process must in this case be regarded as a double jump of a single electron, in which a negative electron jumps to some state of positive energy, and then falls back into the hole that is the original proton. Now it is easy to see that the probability of this

¹ P. Dirac, Roy. Soc. Proc. A126, 360 (1930).

² By a negative electron we mean an electron of negative energy.

scattering is determined by precisely the same matrix components as those which give the electron scattering, and that the present theory gives equal scattering coefficients for electron and proton. Of course, the interaction between electrons is omitted in this computation; but the difficulty is this, that such interaction would affect electron scattering and proton scattering in precisely the same way; whereas the Thomson formula requires the latter to be smaller by a factor proportional to the square of the ratio of the masses.

Finally, there is a numerical discrepancy to be noted. According to Dirac's suggestions, the filling of the proton gaps in the distribution of negative electrons should correspond to the annihilation of an electron and a proton, and should thus, under all normal conditions, be a very rare occurrence. Now if we consider for definiteness a free electron in an enclosure in which there are n_p free protons per unit volume, we may readily compute the rate at which the electron should, by the Dirac radiation theory, fall into one of the corresponding gaps. The conservation laws require that at least two quanta be emitted in this process; and it is sufficient to consider jumps in which no more than two quanta are emitted. The details of the calculation will be published elsewhere; if we neglect the interaction of the electron with the negative

electrons we obtain for the mean life time of the electron:

$$T = Gm^2c^3e^{-4}/n_p \quad (2)$$

where G is a numerical constant of the order of unity, e the charge, and m the mass of the electron. Now again it is difficult to see what large errors could be involved in the computation, since the matrix components which give (2) are of precisely the same type as those which give correctly the Thomson formula and the optical transition probabilities of the electron; and (2) gives a mean life time for ordinary matter of the order of 10^{-10} seconds.

Thus we should hardly expect any states of negative energy to remain empty. If we return to the assumption of two independent elementary particles, of opposite charge and dissimilar mass, we can resolve all the difficulties raised in this note, and retain the hypothesis that the reason why no transitions to states of negative energy occur, either for electrons or protons, is that all such states are filled. In this way, we may accept Dirac's reconciliation of the absence of these transitions with the validity of the scattering formulae.

The Collision Diameter of the Hydrogen Atom

Harteck measured the viscosity of monatomic hydrogen and calculated the collision radius to be $r_H = 1.3 \times 10^{-8}$ cm (r_0 of the first Bohr orbit is 0.53×10^{-8} cm). We have measured the decrease of intensity of a fine beam of monatomic hydrogen in passing through 3.0 cm of mercury vapor at 0.000185 mm Hg and find the decrease of intensity to be 23 percent. If the collisions are supposed to be between elastic spheres the sum of their radii is 6.2×10^{-8} or assuming $r_{Hg} = 1.8 \times 10^{-8}$,

the radius of hydrogen atom is 4.4×10^{-8} . This is larger than would be assumed even on wave mechanics unless there is very considerable resonance interaction between mercury and hydrogen.

Excited Radicals in Chemical Compounds

The letter of Mr. D. H. Andrews in your number of December 15th makes the important point it is possible to assign definite frequencies to vibrating groups in the molecule, and that these frequencies are constant, to a first approximation, from molecule to molecule e.g. the value of the vibration fre-

quency of C-H in any molecule will be of the order of 3000 cm^{-1} , altering only slightly with change of environment. Although some of Mr. Andrews' values are open to question, there is a weight of evidence, both from the Raman effect and from infra-red spectra, for the essential correctness of his statement;

the failure to realise it has been the cause of false analyses of the spectra of several polyatomic molecules, in which the frequency of, say, the CO group has been given values varying from 1500 to 200 cm^{-1} .

It is possible, however, to go much further. First, the frequency of a group, which remaining constant in molecules where the chemical environment is the same, can undergo a sharp change to a second value corresponding to a second chemical environment. I was led to this conception from a study of the building-up of the N_2O molecule from NO. The analysis of the vibration-rotation band system of N_2O (to be published shortly) shows that the molecule is linear and symmetrical. The vibration of N-O along the axis of the molecule is 2250 cm^{-1} . Now the frequency of the NO molecule in its normal ($^2\Pi$) state is 1892 cm^{-1} ; the building of the N_2O molecule has brought about a very definite change. A name can be given to this change when it is realized that the frequency of the first excited ($^2\Sigma$) state of NO is 2345 cm^{-1} . The numerical resemblance is striking; and it becomes more than a coincidence when we find that the only other excited state ($^2\Pi$) so far known has a frequency of 1030 cm^{-1} , and that the Raman effect and infra-red spectra of compounds containing the NO group give a value *c.* 1000 without exception. With these frequencies it is possible to fit all the results upon the NO group at present known i.e. a diatomic group within a polyatomic molecule can be described in terms of the excited states of a diatomic molecule.

The results are even more definite when the CO group is considered. In a normal ketone or acid the vibration frequency is *c.* 1600 cm^{-1} . The Raman evidence is contradictory but the infra-red quite convincing. On the other hand, an α -diketone of the form $\text{R}_2\text{C}(\text{CO})_2$

seems, from the careful analysis of the absorption spectra of several compounds of this type by Louis Light of Zürich, to be of the order of 1100 cm^{-1} .

The first three states of the CO molecule are:

<i>x</i>	$^1\Sigma$	2155
<i>a</i>	$^5\Pi?$	1724
<i>d</i>	$^5\Sigma?$	1105

the agreement is satisfactory. The effect of the conjugated system is particularly interesting.

Certain principles may be set down, even at this early stage:

(i) A diatomic group persists throughout a large number of molecules with the same vibration frequency. As Mr. Andrews suggests, this establishes the identity of covalent bindings. The mass of the atoms to which the diatomic groups are attached is of small importance.

(ii) A diatomic group can have several sharply distinct frequencies. Each of these frequencies behaves as defined in (i).

(iii) The frequencies of a diatomic group correspond to the frequencies of excited states of the appropriate diatomic molecule. A frequency corresponding to the frequency of the normal state of the molecule is not usually observed.

At the moment the attempt to put a spectroscopic name to chemical binding must stop with groups bound by covalencies. Clearly the extension of the idea to such problems as the boron hydrides is practicable; if in the B_2H_6 molecule there are B-H groups bound by singlet linkages, then the frequencies of these groups should not coincide with the frequency of any of the states of the ordinary BH molecule bound by a covalency.

Similarly, the kind of linkage shown to exist by Lennard Jones for the normal ($^3\Sigma$) state of the oxygen molecule should be responsible for abnormalities in the way outlined above. There are indications that the C-C binding in C_2H_2 is such a case; if that is true, it will be possible to indulge in a spectroscopic re-naming of the "triple" bond.

The Glancing Angle of Reflection from Calcite for Silver ($K\alpha_1$) X-rays

We have measured the first order glancing angle at which the $K\alpha_1$ line of silver is reflected from the cleavage planes of calcite

by a method independent of any used by those who have obtained the most reliable results so far. The weighted mean value of

fourteen independent observations reduced to 18°C is $5^{\circ}17'13''.81 \pm 0''.06$.

This value was obtained from spectrograms taken on a new spectrometer specially designed to utilize the displacement method introduced by H. S. Uhler (Phys. Rev. [2] 11, 1-20 (1918)). A full description of the method, instrument and results will be given later.

The value of the wave-length corresponding to the above glancing angle is $0.558238\text{\AA} \pm 0.000002\text{\AA}$, obtained by using 3.02904\AA for the "effective" grating space of calcite (Siegbahn; Spectroscopy of X-Rays, 1924 Edition).

The thermal coefficient of expansion at 18°C for the grating space of calcite obtained from the most reliable sources, without approximations, is $0.0000102\%/^{\circ}\text{C}$. This value differs by about 2% from the generally quoted value originally given by W. Stenström (Dissertation, Lund, 1919) as a sufficient approximation.

It is interesting to note that our value of the glancing angle is $1''.4$ smaller than that given by G. Kellström (Zeits. f. Physik 41, 516 (1927)) for the first order of calcite, viz.

$5^{\circ}17'15''.2$. The probable error of the unweighted mean of Kellström's seven determinations for this order is $\pm 0''.04$. The unweighted mean of his four second order determinations is also larger than ours and has relatively four times this probable error. With such a difference existing one wonders if the grating spaces of the crystal specimens used were the same. We employed an unusually selective piece of calcite which was cleaved from an excellent specimen of Iceland spar contained in the Marsh collection of Yale University.

Our value is larger than those of K. Lang (Ann. d. Physik 75, 489 (1924)), A. Leide (Dissertation, Lund (1925) and A. P. Weber (Zeits. f. Wiss. Photo. 23, 149 (1925)) although coming within $0''.11$ of Lang's and $0''.36$ of Leide's results when their probable errors are added to their respective mean values.

BOOK REVIEWS

Quantum Mechanics. E. U. CONDON AND P. M. MORSE. Pp. 250+xiii, figs. 28. International Series in Physics, McGraw-Hill Book Co., New York, 1929. Price \$3.00.

This is the first book of American authorship on the new science of quantum mechanics and should find a host of readers both here and abroad. It meets the widely felt need for an introductory text making no pretense at completeness, but aiming through numerous illustrative applications and exercises to give the reader a working knowledge of the methods of the quantum theory of today. The authors have kept the work, to use their own words, "on as elementary a plane as possible," but they have not descended to sloppy procedure in their anxiety to make easy reading.

The subject is approached from the standpoint of the statistical interpretation of the Schrödinger theory and the first three quarters of the volume is devoted to an exposition of results obtainable from the Schrödinger wave equation with a minimum of mathematical machinery. A subsequent chapter, however, gives a well written introductory account of the general formulation of the theory by Jordan, Dirac, and von Neuman, which should be helpful to many who have had difficulty in digesting the original papers on this subject.

The rather extensive treatment of diatomic molecules will be most useful to workers in the field of band spectra as there is at present no comprehensive work on the quantum mechanics of molecules. Much of the material in this chapter is derived from the valuable researches of the authors. The reviewer notes with especial pleasure the inclusion of a simplified account of the basic molecular perturbation theory of Born and Oppenheimer worked out directly for the important diatomic case.

The book also contains an interesting chapter on aperiodic phenomena.

The authors lay little emphasis on the philosophical aspect of the quantum mechanics and ignore almost completely many important phases of the subject such as the "electron spin" and the problem of dispersion. These omissions are to be reckoned a virtue rather than a drawback, however, since they enable the authors to deal with the fundamentals of the subject in a leisurely way which will be welcome to the beginner.

EDWIN C. KEMBLE

Outlines of Biochemistry. R. A. GORTNER. Pp. xv and 793. New York, Wiley and Sons; London, Chapman and Hall; 1929. Price \$6.00.

Treatises in biochemistry are the successors of medical textbooks of physiological chemistry; these dealt almost exclusively with mammalian metabolism, foods, enzymes, excreta and the blood; and although when vitamins were recognized and the part played by the secretions of the endocrine glands, these matters were included, the chemistry of the life processes of plants was always beyond their scope. Even with such restrictions on the subject matter, the "conservation of energy" was referred to when dealing with the measurement of animal heat, a formula or two of chemical kinetics got in to ornament the chapter on digestion, and mention was made of the freezing-points of serums and of urine; but—with an eye, no doubt, to the limitations of the medical student—such topics received in general but incidental mention.

It is a far cry from such a book to Professor Gortner's "Outlines." He has a section on the proteins of course, including chapters on the amino-acids and the polypeptides, an up-to-date account of the vitamins written by Professor L. S. Palmer, chapters on the carbohydrates and the fats and oils, and others on the tannins and on the colouring matters of plants; but the first 290 pages of his book are devoted to "The colloidal state of matter." Here the preparation and characteristic properties of colloids are described, their electro-kinetic behaviour, and their behaviour with electrolytes and among themselves; there is a chapter on gels, and one each on hydrogen-ion-concentration, surface-tension, osmotic-pressure, and "the Donnan equilibrium."

It is obvious that in this book the generalizations of physical chemistry are not slipped in as "explanations" of an isolated fact or two, but have the place of honour; in their light the facts of physiology are examined—not mammalian alone, for as might be expected from a professor of agricultural biochemistry the plant receives its due.

To readers of *The Physical Review* the illustrations here afforded of the scope and power of generalizations long familiar should prove intensely interesting. Who that measures vapour-tensions will not enjoy the picture of the cactus on the wall in desert Arizona ten months without rain and sheltered from the dew, or the story of the three-months sojourn of another cactus over sulphuric acid, the account of drought-resisting cereals in Utah, winter-hardy wheat, and the drying-up of earthworms, or the human-interest paragraphs on the granary-weevils' life without a drink, the new oedema diagnosis, and the rigor of our bodies after death? All these and more are brought into the chapter on Gels to illustrate "imbibition" and the distinction between "bound" and "liquid" water; and not as incidental illustrations merely, for they are examined in the light of tables, formulas and charts, and correlated with freezing-points, osmotic-pressures and absorption in the infra-red. Therefore, if any Reader thinks he knows more physics though less biology than Gortner, let him go to it; the door is opened wide.

The sample given above could easily be matched; literature citations show where synoptic papers can be found; it would be a shame to let mere biochemists monopolize the reading of this book.

W. LASH MILLER

Introduction to Physical Optics. JOHN KELLOCK ROBERTSON. Pp. 422, figs 222. D. Van Nostrand Co., New York 1929. Price \$4.00.

This is a text-book which is intermediate in grade between the elementary and the advanced optics texts. A small amount of differential calculus is used, but otherwise the mathematics required consists of the usual trigonometry, algebra, and geometry. A large number of problems are given, the answers to which are found at the end of the book. Several problems are solved in great detail in the text.

A very commendable feature is the use of photographic illustrations of the various optical phenomena such as interference and diffraction bands, and spectra. These show the various types of band systems obtained with different types of apparatus, giving the student a clear impression of the phenomena under discussion. The photographs are all good except the one of interference rings in polarized light.

In trying to be neither too conservative, nor radical, the author seems to overemphasize the conflict between the corpuscular and wave theories of light. Naturally, most of the phenomena treated require the wave theory. The nature of waves and the composition of vibrations is fully and clearly discussed in an early chapter. The principles thus established are later applied to the treatment of interference, diffraction, and elliptical polarization. The Cornu spiral is explained in a graphical, qualitative manner, and is used to explain some of the Fresnel diffraction phenomena.

The quantum theory and the foundations of Bohr's theory of spectra are briefly reviewed. There are also a few paragraphs on wave mechanics and the diffraction of electron waves, which give a rather belated suggestion of the duality of radiation as well as matter. Optical phenomena due to motion are discussed in the closing chapter.

JOSEPH VALASEK

Elementary Differential Equations. THORNTON C. FRY. Pp. x+255, figs. 42. New York, D. Van Nostrand Co., 1929. Price, \$2.50.

This textbook gives a pleasing treatment of its subject of the grade of difficulty that is adapted to junior courses in the better American engineering colleges. It is distinguished by careful presentation of the fundamentals, recognizing that while applications of the subject in physics and engineering are of the highest value, nevertheless, "They are not without their danger, however, if they are used unwisely, for should the student come to rely upon his physical intuition as a substitute for abstract logic, rather than as an aid to it, he would have missed half the benefit of the study." (Preface).

There is a good treatment of operational methods of handling linear equations with constant coefficients, and systems of them, with emphasis on the applications to electrical circuit theory.

E. U. CONDON

Die Grundlage der allgemeinen Relativitätstheorie. A. EINSTEIN. Pp. 64. Fifth unaltered printing. J. A. Barth. Leipzig, 1929.

This is a fifth unaltered printing of Einstein's famous 1916 treatment of the foundations of the general theory of relativity. It was first published, except for the table of contents, as a single article in volume 49 of the *Annalen der Physik*, and was the first systematic treatment of general relativity, providing the complete mathematical and theoretical foundation leading to the three tests of the theory furnished by the rotation of the perihelion of Mercury, the bending of light in passing through the gravitational field of the sun, and the red shift for light from the surface of the sun. The paper is not only a document of the greatest historical interest, but also still furnishes one of the best introductions to general relativity and contains the three conclusions of the theory for which we have the most direct experimental evidence.

RICHARD C. TOLMAN

THE PHYSICAL REVIEW

SEPARATION OF ANGLES IN THE TWO-ELECTRON PROBLEM

By G. BREIT

DEPARTMENT OF PHYSICS, NEW YORK UNIVERSITY

(Received February 3, 1930)

ABSTRACT

Neglecting the spin, two electrons are described in quantum mechanics by means of a wave equation in six variables. It is shown that well-known relations between angular momentum operators make it possible to determine the dependence of the wave function on three variables. The problem is thus reduced from *six* to *three* dimensions. For a state with an assigned "orbital" angular momentum l , say an S , P , D state the dependence of the wave function on three Euler angles is determined by the value of l . The wave function is a linear combination of products of distance and angle functions, the latter depending only on the three Euler angles. The angle functions are well-known solutions of the wave equation for a symmetrical top. The distance functions satisfy wave equations in three variables r_1, r_2, r_{12} or r_1, r_2, θ . The case of P terms is worked out in detail. Equations (10), (25) apply to two electrons having the *same azimuthal quantum number*. Equations (18), (20), (24) describe all the other cases, for instance S and P electrons combining to give 1P and 3P . Triplets are described by (18) and singlets by (20).

TWO electrons are treated in quantum mechanics by means of a six dimensional wave equation. In most atomic problems it is sufficient to consider the two electrons under the influence of a central field of force and to treat all other questions by perturbation methods. It is well known that in this approximation essential simplifications are introduced by the spherical symmetry of the central field of force. The eigenfunctions may be arranged in non-combining systems, each system corresponding to a certain value of the total angular momentum. By considerations of this sort it has been shown that correct space quantization, multiplet intensity relations, selection rules, and anomalous Zeeman effect formulas are consequences of quantum mechanics.†

In the calculations of the two or many electron problem it is customary at present to employ an approximation method such as Hartree's and to

† See in particular E. Wigner, *Zeits. f. Physik* **43**, 624 (1927) and especially p. 640 where the general possibility of (6) below is pointed out. The difference between the present treatment and Wigner's lies in the use of (4) with its known system of eigenfunctions.

consider each electron as subject to the action of a central field of force. In the calculations of the normal energy levels of He, however, Hylleraas¹ found it useful to consider the problem exactly. His calculations apply to the S states, which reduces the problem to a three dimensional one. We shall see that the reduction from six to three dimensions can be always made and that it is an immediate consequence of the spherical symmetry of the field. Even though the solution of a three dimensional wave equation is difficult we believe to have simplified the general problem because the application of variational methods, such as the Ritz method to a six or five dimensional problem is usually out of the question.

Let ψ be the Schroedinger function. Let the coordinates of the electrons be $(x_1, y_1, z_1), (x_2, y_2, z_2)$. By the general theorem of conservation of angular momentum

$$\left[\sum_{x,y,z} \left(y_1 \frac{\partial}{\partial z_1} - z_1 \frac{\partial}{\partial y_1} + y_2 \frac{\partial}{\partial z_2} - z_2 \frac{\partial}{\partial y_2} \right) + l(l+1) \right] \psi = 0 \quad (1)$$

for any state with angular momentum l . Introducing polar coordinates $(r_1, \theta_1, \phi_1), (r_2, \theta_2, \phi_2)$ this becomes

$$\begin{aligned} & \left\{ \left(\sin \phi_1 \frac{\partial}{\partial \theta_1} + \cos \phi_1 \frac{\cos \theta_1}{\sin \theta_1} \frac{\partial}{\partial \phi_1} + \sin \phi_2 \frac{\partial}{\partial \theta_2} + \cos \phi_2 \cot \theta_2 \frac{\partial}{\partial \phi_2} \right)^2 \right. \\ & \quad + \left(-\cos \phi_1 \frac{\partial}{\partial \theta_1} + \sin \phi_1 \cot \theta_1 \frac{\partial}{\partial \phi_1} - \cos \phi_2 \frac{\partial}{\partial \theta_2} + \sin \phi_2 \cot \theta_2 \frac{\partial}{\partial \phi_2} \right)^2 \\ & \quad \left. + \left(\frac{\partial}{\partial \phi_1} + \frac{\partial}{\partial \phi_2} \right)^2 + l(l+1) \right\} \psi = 0. \quad (2) \end{aligned}$$

We now reexpress ψ in terms of Euler angles θ', ϕ', ϕ and r_1, r_2, θ connected by the transformation formulas:

$$\theta' = \theta_1, \quad \phi' = \phi_1$$

$$\begin{aligned} \cos \theta &= \cos \theta' \cos \theta_2 + \sin \theta' \sin \theta_2 \cos (\phi_2 - \phi_1); & \sin \theta_2 \sin \alpha &= \sin \theta' \sin \phi \\ \cos \theta_2 &= \cos \theta' \cos \theta - \sin \theta' \sin \theta \cos \phi; & \sin \theta \sin \alpha &= \sin \theta' \sin (\phi_2 - \phi_1) \\ \cos \theta' &= \cos \theta_2 \cos \theta + \sin \theta_2 \sin \theta \cos \alpha; & \sin \theta \sin \phi &= \sin \theta_2 \sin (\phi_2 - \phi_1) \end{aligned} \quad (3)$$

the notation being throughout as in the first paper of Hylleraas. The angle θ drops out of (2) which reduces itself to

$$\left\{ \frac{\partial^2}{\partial \theta'^2} + \cot \theta' \frac{\partial}{\partial \theta'} + \frac{1}{\sin^2 \theta'} \frac{\partial^2}{\partial \phi'^2} - 2 \frac{\cos \theta'}{\sin^2 \theta'} \frac{\partial^2}{\partial \phi \partial \phi'} + \frac{1}{\sin^2 \theta'} \frac{\partial^2}{\partial \phi'^2} + l(l+1) \right\} \psi = 0. \quad (4)$$

¹ Hylleraas, Zeits. f. Physik 54, 347 (1929); 48, 469 (1928). See also J. C. Slater, Proc. Nat. Acad. 13, 423 (1927); G. W. Kellner, Zeits. f. Physik 44, 91 (1927).

² For derivation see appendix I.

This is a well-known equation, being a special case of the wave equation for a symmetrical top. Its eigenwerte are known to correspond to integral values of l , the value zero being included. The angular momentum about the z axis is represented by the operator

$$M^z = \frac{\hbar}{2\pi i} \left(x_1 \frac{\partial}{\partial y_1} - y_1 \frac{\partial}{\partial x_1} + x_2 \frac{\partial}{\partial y_2} - y_2 \frac{\partial}{\partial x_2} \right) = \frac{\hbar}{2\pi i} \left(\frac{\partial}{\partial \phi_1} + \frac{\partial}{\partial \phi_2} \right) = \frac{\hbar}{2\pi i} \frac{\partial}{\partial \phi'}. \quad (5)$$

If $l(l+1)=0$ there are no eigenfunctions (4) except those which do not depend on θ' , ϕ , ϕ' . Thus for $l=0$ the wave function depends only on r_1 , r_2 , θ or r_1 , r_1 , r_{12} as pointed out by Hylleraas for S states. In all other cases i.e. for P , D , states ψ depends on the angles. Thus for P states ($l=1$) we have the following nine independent eigenfunctions

$$\cos \theta', (1 + \cos \theta') e^{\pm i(\phi + \phi')}, e^{\pm i\phi} \sin \theta', e^{\pm i\phi'} \sin \theta', (1 - \cos \theta') e^{\pm i(\phi - \phi')}.$$

We may say therefore that for any P state

$$\psi = \sum_{i=1}^9 f_i(r_1, r_2, \theta) u_i(\theta', \phi', \phi) \quad (6)$$

where u_1, \dots, u_9 are the above set of nine independent eigenfunctions. Equation (6) is, however, too general because the nine eigenfunctions can be subdivided into three non-combining sets, each set containing three functions, all the functions of a given set depending on ϕ' as $e^{im\phi'}$. According to (5) each set describes such an orientation of the total angular momentum that its component along OZ is $m\hbar/2\pi$. For $m=0$ such a set of functions is

$$\cos \theta', e^{\pm i\phi} \sin \theta'. \quad (6')$$

In (6) therefore, it is permissible to extend the summation only over these three functions if we are interested only in solutions with $m=0$. The legitimacy of using only these three functions is of course a consequence of the invariance of the Hamiltonian under rotations about the z axis. On account of this invariance the result of operating by the Hamiltonian on any term in (6) gives rise to angular functions with the same value of m . In the general expression (6) therefore each set of functions is entirely independent of the other two.

Since the two electrons are equal we have a further subdivision into non-combining term systems. This is the usual subdivision into symmetric and antisymmetric solutions. With this in mind we use Hylleraas' expressions (23), (24) according to which the Schroedinger equation for the energy is

$$\begin{aligned} & \frac{1}{r_1^2} \frac{\partial}{\partial r_1} \left(r_1^2 \frac{\partial \psi}{\partial r_1} \right) + \frac{1}{r_2^2} \frac{\partial}{\partial r_2} \left(r_2^2 \frac{\partial \psi}{\partial r_2} \right) + \frac{1}{r_1^2} \left[\frac{1}{\sin \theta} \frac{\partial}{\partial \theta} \left(\sin \theta \frac{\partial \psi}{\partial \theta} \right) + A_1[\psi] \right] \\ & + \frac{1}{r_2^2} \left[\frac{1}{\sin \theta} \frac{\partial}{\partial \theta} \left(\sin \theta \frac{\partial \psi}{\partial \theta} \right) + A_2[\psi] \right] + 8\pi^2 m \hbar^{-2} (E - V) \psi = 0 \end{aligned}$$

$$\begin{aligned}
A_1[\psi] = & (\cot^2 \theta + 2 \cot \theta \cot \theta' \cos \phi + \cot^2 \theta') \frac{\partial^2 \psi}{\partial \phi^2} + \frac{1}{\sin \theta'} \frac{\partial}{\partial \theta'} \left(\sin \theta' \frac{\partial \psi}{\partial \theta'} \right) \\
& + \frac{1}{\sin^2 \theta'} \frac{\partial^2 \psi}{\partial \phi'^2} + 2 \cot \theta' \sin \phi \frac{\partial^2 \psi}{\partial \theta \partial \phi} - 2 \cos \phi \frac{\partial^2 \psi}{\partial \theta \partial \theta'} - 2 \frac{\sin \phi}{\sin \theta'} \frac{\partial^2 \psi}{\partial \theta \partial \phi'} \\
& + 2 \cot \theta \sin \phi \frac{\partial^2 \psi}{\partial \phi \partial \theta'} - \frac{2}{\sin \theta'} (\cot \theta' + \cot \theta \cos \phi) \frac{\partial^2 \psi}{\partial \phi \partial \phi'}; \quad A_2[\psi] = \frac{1}{\sin^2 \theta} \frac{\partial^2 \psi}{\partial \phi^2} \quad (7)
\end{aligned}$$

On account of spherical symmetry V is a function of r_1, r_2, θ only and does not contain θ', ϕ', ϕ . The functions u_i behave therefore as constant coefficients with the exceptions of the terms $A_1[\psi], A_2[\psi]$. Since by (3) $\sin \theta' \sin \phi = \sin \theta_2 \sin \alpha$, the angular eigenfunction $\sin \theta' \sin \phi$ is seen to be antisymmetric in the electrons 1 and 2. For this reason A_1 and A_2 must produce similar effects on it. In fact it is found that

$$A_1[\sin \theta' \sin \phi] = A_2[\sin \theta' \sin \phi] = -\sin^{-2} \theta (\sin \theta' \sin \phi). \quad (8)$$

We see therefore that the particular linear combination of two of the eigenfunctions for $m=0$, namely $\sin \theta' \sin \phi$ when operated on by the Hamiltonian gives rise to itself only. A possible P state is therefore given by

$$\psi = f(r_1, r_2, \theta) \sin \theta' \sin \phi \quad (9)$$

and the differential equation for f is

$$\begin{aligned}
& \frac{\partial}{r_1^2 \partial r_1} \left(r_1^2 \frac{\partial f}{\partial r_1} \right) + \frac{\partial}{r_2^2 \partial r_2} \left(r_2^2 \frac{\partial f}{\partial r_2} \right) + (r_1^{-2} + r_2^{-2}) \left[\frac{\partial}{\sin \theta \partial \theta} \left(\sin \theta \frac{\partial f}{\partial \theta} \right) - \frac{f}{\sin^2 \theta} \right] \\
& + 8\pi^2 m \hbar^{-2} (E - V) f = 0. \quad (10)
\end{aligned}$$

This differential equation differs from the one for S states only by the term $-(r_1^{-2} + r_2^{-2}) \sin^{-2} \theta$ and it is seen that the determination of its eigenvalues can be carried out by analogous methods. The physical interpretation of the solutions (9) becomes apparent if the perturbation e^2/r_{12} between the two electrons is supposed small. Then (10) is separable. Supposing the separation to take place by

$$f = P_n^{(1)}(\cos \theta) g(r_1, r_2) \quad (10')$$

we obtain

$$\frac{\partial}{r_1^2 \partial r_1} \left(r_1^2 \frac{\partial f}{\partial r_1} \right) + \frac{\partial}{r_2^2 \partial r_2} \left(r_2^2 \frac{\partial f}{\partial r_2} \right) - n(n+1)(r_1^{-2} + r_2^{-2}) f + 8\pi^2 m \hbar^{-2} (E - V) f = 0.$$

This may be considered as the radial part of the Schroedinger equation for two electrons, each being initially in a state with azimuthal quantum number n . The same may be seen from (10') because by (3)

$$\sin \theta \sin \theta' \sin \phi = \sin \theta_1 \sin \theta_2 \sin (\phi_2 - \phi_1)$$

so that the angular part of (10') is a linear combination of products of the type $P_n^1(\cos \theta_1) e^{\pm i\phi_1}$. The solution (9) represents therefore P states which arise either from two 2P or two 2D or two 2F electrons etc. The solutions of (10) may be symmetric or antisymmetric in r_1, r_2 giving the singlet and triplet systems. They include the case of equivalent orbits.

Out of the three functions (6') we have left now only two

$$\cos \theta', \sin \theta' \cos \phi$$

substituting these into (7) it is found that the Hamiltonian operating on one of them gives rise not only to itself but also to the other. Here we must write

$$\psi = f_1 \cos \theta' + f_2 \sin \theta' \cos \phi. \quad (11)$$

Operating on this by (7) we get two simultaneous linear equations in f_1 and f_2 :

$$\begin{aligned} L[f_1] - 2r_1^{-2} \left(f_1 + \cot \theta f_2 + \frac{\partial f_2}{\partial \theta} \right) &= 0 \\ L[f_2] + r_1^{-2} \left(2 \frac{\partial f_1}{\partial \theta} - \sin^{-2} \theta f_2 \right) - r_2^{-2} \sin^{-2} \theta f_2 &= 0 \end{aligned} \quad (12)$$

where

$$\begin{aligned} L[f] &= \frac{\partial}{r_1^2 \partial r_1} \left(r_1^2 \frac{\partial f}{\partial r_1} \right) + \frac{\partial}{r_2^2 \partial r_2} \left(r_2^2 \frac{\partial f}{\partial r_2} \right) \\ &+ (r_1^{-2} + r_2^{-2}) \frac{\partial}{\sin \theta \partial \theta} \left(\sin \theta \frac{\partial f}{\partial \theta} \right) + 8\pi^2 m h^{-2} (E - V) f. \end{aligned} \quad (13)$$

Equations (11), (12) are unsymmetrical in (1) and (2). Making the substitutions

$$F_1 = f_1 + \cot \theta \cdot f_2, \quad F_2 = (\sin \theta)^{-1} f_2 \quad (14)$$

we have

$$\psi = F_1 \cos \theta_1 - F_2 \cos \theta_2 \quad (15)$$

while (12) goes into³

$$\begin{aligned} L[F_1] + \frac{2}{r_1^2} \left(\cot \theta \frac{\partial F_1}{\partial \theta} - F_1 \right) + \frac{2 \partial F_2}{r_2^2 \sin \theta \partial \theta} &= 0 \\ L[F_2] + \frac{2 \partial F_1}{r_1^2 \sin \theta \partial \theta} + \frac{2}{r_2^2} \left(\cot \theta \frac{\partial F_2}{\partial \theta} - F_2 \right) &= 0. \end{aligned} \quad (16)$$

Here F_1, F_2 are functions of r_1, r_2, θ only. Any ψ in (15) must be either symmetric or antisymmetric in (1) and (2). The latter case is obtained if

$$F_2(r_1, r_2, \theta) = F_1(r_2, r_1, \theta) \equiv \tilde{F}(r_1, r_2, \theta). \quad (17)$$

³ For direct derivation see Appendix II.

Letting $F = F_1$ the two equations (16) reduce to a single equation in F viz.

$$L[F] + \frac{2}{r_1^2} \left(\cot \theta \frac{\partial F}{\partial \theta} - F \right) + \frac{2}{r_2^2 \sin \theta} \frac{\partial \tilde{F}}{\partial \theta} = 0. \quad (18)$$

The symmetric solutions are obtained by letting

$$F_2 = -\tilde{F}_1. \quad (19)$$

Here we write $F_1 = G$ and (16) reduces again to a single equation

$$L[G] + \frac{2}{r_1^2} \left(\cot \theta \frac{\partial G}{\partial \theta} - G \right) - \frac{2}{r_2^2 \sin \theta} \frac{\partial \tilde{G}}{\partial \theta} = 0. \quad (20)$$

The only difference between (18) and (20) is in the sign of the last term. This term represents the resonance between the two electrons. In the unperturbed state i.e. if the perturbation term e^2/r_{12} is not important the simplest solutions of (18) are those for which $(\partial F/\partial \theta) = 0$. Then (15) shows that we deal with a 3P term arising from a 2S and a 2P electron while similarly the solutions of (20) give the corresponding 1P terms. In addition to these solutions there are others for the unperturbed case. Thus if we set

$$F = g(r_1, r_2) \cos \theta + \tilde{g}/3$$

we find from (15) that

$$\psi = g(\cos \theta \cos \theta_1 - \cos \theta_2/3) - \tilde{g}(\cos \theta \cos \theta_2 - \cos \theta_1/3).$$

Since

$$\cos \theta \cos \theta_1 - \cos \theta_2/3 = \frac{2}{3} \cos \theta_2 P_2(\cos \theta_1) - \cos \theta_1 \sin \theta_1 \sin \theta_2 \cos(\phi_2 - \phi_1)$$

this angular function is seen to consist of a linear combination of

$$e^{\pm i m \phi_1} P_2^m(\cos \theta_1) \quad \text{and} \quad e^{\pm i m \phi_2} P_1^m(\cos \theta_2).$$

This is a case of 3P and 2D terms combining to give a 3P . In a similar way all other combinations between electrons of unequal azimuthal quantum number resulting in P terms are contained among the solutions of (18).

Summarizing the classifications of all solutions belonging to the subset (6') we may say that (9) and (10) give the P terms arising from electrons which in the unperturbed state have equal azimuthal quantum numbers while (15), (18), (20) give the P terms arising from all other electron combinations.

It will be remembered now that equation (6) contains two more non-combining sets of eigenfunctions corresponding to $m = \pm 1$. The spherical symmetry of the problem enables us to write them down by analogy with those already found. Thus corresponding to (15) and (18) we have now a complete set of orthogonal eigenfunctions

$$\begin{aligned}
u_1 &= (3^{1/2}/4\pi)(F \sin \theta_1 e^{i\phi_1} - \tilde{F} \sin \theta_2 e^{i\phi_2}) \\
&= (3^{1/2}/4\pi)[a \sin \theta' + b(-i \sin \phi - \cos \theta' \cos \phi)]e^{i\phi'} \\
u_0 &= (6^{1/2}/4\pi)(F \cos \theta_1 - \tilde{F} \cos \theta_2) = (6^{1/2}/4\pi)[a \cos \theta' + b \sin \theta' \cos \phi] \quad (21) \\
u_{-1} &= (3^{1/2}/4\pi)(F \sin \theta_1 e^{-i\phi_1} - \tilde{F} \sin \theta_2 e^{-i\phi_2}) \\
&= (3^{1/2}/4\pi)[a \sin \theta' + b(i \sin \phi - \cos \theta' \cos \phi)]e^{-i\phi'} \\
a &= F - \tilde{F} \cos \theta, \quad b = \tilde{F} \sin \theta.
\end{aligned}$$

The normalization being such that

$$\int (F^2 - 2F\tilde{F} \cos \theta + \tilde{F}^2) dV_{r_1, r_2, \theta} = 1; \quad dV_{r_1, r_2, \theta} = r_1^2 r_2^2 \sin \theta dr_1 dr_2 d\theta.$$

These three eigenfunctions belong to the eigenwerte of (18) and are to be used together in solving perturbation problems such as fine structure calculations. Similarly there are three other eigenfunctions for every solution of (20). The remaining three functions are of the type (9). We note that $\sin \theta \sin \phi = R_z/R$ where $R_z = [\tilde{r}_1 \times \tilde{r}_2]$. Forming the combinations $R_z \pm iR_y$ we find this set of functions to be

$$\begin{aligned}
&[(3^{1/2}/4\pi)e^{i\phi'}(i \cos \phi - \cos \theta' \sin \phi), \quad (6^{1/2}/4\pi) \sin \theta' \sin \phi, \\
&(3^{1/2}/4\pi)e^{-i\phi'}(-i \cos \phi - \cos \theta' \sin \phi)]f. \quad (22)
\end{aligned}$$

The differential equations (16), (18) and the corresponding sets of eigenfunctions (21), (22) correspond to essentially different cases and for this reason the variational equations belonging to the two cases are different. We consider the type of solution described by (16) and (21) first. The variational equation belonging to the problem is

$$\delta \int \left\{ \left(\frac{\partial \psi}{\partial x_1} \right)^2 + \dots + \left(\frac{\partial \psi}{\partial z_2} \right)^2 + 8\pi^2 m \hbar^{-2} (V - E) \psi^2 \right\} dx_1 \dots dz_2 = 0 \quad (23)$$

with the equation of condition

$$\int \psi^2 dx_1 \dots dz_2 = 1. \quad (23')$$

Here $dx_1 \dots dz_2$ is the volume element of the six dimensional configuration space. Taking any of the functions (21) the volume element may be reexpressed in terms of $r_1, r_2, \theta, \theta', \phi'$ and the integrations may then be performed over the angles θ', ϕ' in (23) and (23').

The result of the calculation is:⁴

$$\begin{aligned}
&\delta \int \left\{ \left(\frac{\partial F_1}{\partial r_1} \right)^2 - 2 \cos \theta \frac{\partial F_1}{\partial r_1} \frac{\partial F_2}{\partial r_1} + \left(\frac{\partial F_2}{\partial r_1} \right)^2 + \left(\frac{\partial F_1}{\partial r_2} \right)^2 - 2 \cos \theta \frac{\partial F_1}{\partial r_2} \frac{\partial F_2}{\partial r_2} + \left(\frac{\partial F_2}{\partial r_2} \right)^2 \right. \\
&\quad \left. + (r_1^{-2} + r_2^{-2}) \left[\left(\frac{\partial F_1}{\partial \theta} \right)^2 - 2 \cos \theta \frac{\partial F_1}{\partial \theta} \frac{\partial F_2}{\partial \theta} + \left(\frac{\partial F_2}{\partial \theta} \right)^2 \right] + 2r_1^{-2} F_1^2 + 2r_2^{-2} F_2^2 \right\}
\end{aligned}$$

⁴ For derivation see appendix II.

$$\begin{aligned}
& + 2r_1^{-2} \sin \theta F_1 \frac{\partial F_2}{\partial \theta} + 2r_2^{-2} \sin \theta F_2 \frac{\partial F_1}{\partial \theta} \\
& + 8\pi^2 m \hbar^{-2} (V - E) (F_1^2 - 2F_1 F_2 \cos \theta + F_2^2) \} dV_{r_1, r_2, \theta} = 0
\end{aligned} \quad (24)$$

and the equation of condition is

$$\int (F_1^2 - 2F_1 F_2 \cos \theta + F_2^2) dV_{r_1, r_2, \theta} = 1. \quad (24')$$

Performing independent variations of F_1 and F_2 the differential equations (16) follow from (24). Corresponding to (17) and (18) the variational equation (24) gives two different equations, one applying to an antisymmetric ψ and the other to the symmetric one. Each of these involves only one function and its transposed and can be worked out by the same method as used by Hylleraas. It will be noted that the antisymmetric solutions (24) involve combinations of the type $F^2 - 2F\bar{F} \cos \theta + \bar{F}^2$. If $r_1 = r_2$, this vanishes for $\theta = 0$, so that the values of $F(r, r, \theta)$ are not important. On the other hand for the symmetric solutions $G(r, r, \pi)$ are not important. It will be noted also that both the differential equation and the variational one involve simultaneously a function of r_1, r_2, θ and its transposed and that *the dependence on θ is of primary importance in determining the difference between symmetric and antisymmetric solutions.*

The variational equation corresponding to (10) can be written down by inspection and is

$$\begin{aligned}
\delta \int \left\{ \left(\frac{\partial f}{\partial r_1} \right)^2 + \left(\frac{\partial f}{\partial r_2} \right)^2 + (r_1^{-2} + r_2^{-2}) \left[\left(\frac{\partial f}{\partial \theta} \right)^2 + \frac{f^2}{\sin^2 \theta} \right] \right. \\
\left. + 8\pi^2 m \hbar^{-2} (V - E) f^2 \right\} dV_{r_1, r_2, \theta} = 0 \quad (25)
\end{aligned}$$

with the equation of condition

$$\int f^2 dV_{r_1, r_2, \theta} = 1. \quad (25')$$

This differs from the equation used by Kellner and Hylleraas only by the term $(r_1^{-2} + r_2^{-2}) \cdot f^2 / \sin^2 \theta$. Obvious changes of variables to r_1, r_2, r_{12} can of course be made and the elliptic coordinates used by Hylleraas can be introduced here with the same boundary conditions.

Only P terms have been considered here. It is clear, however, that the same can be done for any other value of l . Since closed expressions for the general case are complicated, we do not consider them here.

APPENDIX

(I) Derivation of equation (4)

This can be derived either by the analytical procedure indicated in the text or else by the following geometrical consideration. The first three terms in (2) are squares of infinitesimal rotation operators about the axes x, y, z . The changes in ψ during a rotation are brought about

only through its dependence on θ' , ϕ' , ϕ . We draw two lines ON , OM in the xy plane with azimuths $-\pi/2 + \phi$, ϕ . Resolving a rotation about OX along ON and OM with $ON \perp OM$ the first contributes $\sin \phi' \partial/\partial\theta'$. The second must be compounded as a sum of rotations along OZ and $O(1)$ and give rise to

$$\cos \phi' (\cot \theta' (\partial/\partial\phi') - (\partial/\sin \theta' \partial\phi))$$

The rotation operators are thus found to be

$$\begin{aligned} L_x &= \sin \phi' \frac{\partial}{\partial\theta'} + \cos \phi' \left(\cot \theta' \frac{\partial}{\partial\phi'} - \frac{\partial}{\sin \theta' \partial\phi} \right), \\ L_y &= -\cos \phi' \frac{\partial}{\partial\theta'} + \sin \phi' \left(\cot \theta' \frac{\partial}{\partial\phi'} - \frac{\partial}{\sin \theta' \partial\phi} \right), \\ L_z &= \frac{\partial}{\partial\phi'}. \end{aligned}$$

Equation (4) is then obtained as

$$[L_x^2 + L_y^2 + L_z^2 + l(l+1)]\psi = 0.$$

Usual commutation relations between rotation operators are of course also satisfied by L_x , L_y , L_z .

(II) Derivation of (16) and (24).

On account of spherical symmetry it is sufficient to calculate the variational equation for

$$\psi = F_1 - F_2 \cos \theta = a \cos \theta' + b \sin \theta' \cos \phi$$

where

$$a = F_1 - F_2 \cos \theta, \quad b = F_2 \sin \theta.$$

The equation to be transformed is (23). The volume element is

$$dx_1 \cdots dz_2 = r_1^2 r_2^2 \sin \theta \sin \theta' dr_1 dr_2 d\theta d\theta' d\phi d\phi'.$$

We have

$$\begin{aligned} (\text{grad}_1 \psi)^2 &= \left(\frac{\partial \psi}{\partial r_1} \right)^2 + r_1^{-2} \left[\left(\frac{\partial \psi}{\partial \theta_1} \right)^2 + (\sin \theta_1)^{-2} \left(\frac{\partial \psi}{\partial \phi_1} \right)^2 \right] \\ \frac{\partial \psi}{\partial \theta_1} &= -F_1 \sin \theta_1 + \left(\frac{\partial F_1}{\partial \theta} \cos \theta_1 - \frac{\partial F_2}{\partial \theta} \cos \theta_2 \right) \frac{\partial \theta}{\partial \theta_1} \\ \frac{\partial \psi}{\partial \phi_1} &= \left(\frac{\partial F_1}{\partial \theta} \cos \theta_1 - \frac{\partial F_2}{\partial \theta} \cos \theta_2 \right) \frac{\partial \theta}{\partial \phi_1}. \end{aligned}$$

Remembering now that

$$\left(\frac{\partial \theta}{\partial \theta_1} \right)^2 + \frac{1}{\sin^2 \theta_1} \left(\frac{\partial \theta}{\partial \phi_1} \right)^2 = 1 \quad (a)$$

we have:

$$\begin{aligned} \left(\frac{\partial \psi}{\partial \theta_1} \right)^2 + \frac{1}{\sin^2 \theta_1} \left(\frac{\partial \psi}{\partial \phi_1} \right)^2 &= F_1^2 \sin^2 \theta_1 + \left(\frac{\partial F_1}{\partial \theta} \cos \theta_1 - \frac{\partial F_2}{\partial \theta} \cos \theta_2 \right)^2 \\ &\quad - 2F_1 \sin \theta_1 \frac{\partial \theta}{\partial \theta_1} \left(\frac{\partial F_1}{\partial \theta} \cos \theta_1 - \frac{\partial F_2}{\partial \theta} \cos \theta_2 \right). \end{aligned}$$

Substituting the value for $\partial\theta/\partial\theta_1$ which follows from the first equation (3) and using the second equation (3)

$$\sin \theta_1 \frac{\partial \theta}{\partial \theta_1} = -\sin \theta' \cos \phi$$

Writing further

$$a' = \frac{\partial F_1}{\partial \theta} - \frac{\partial F_2}{\partial \theta} \cos \theta, \quad b' = \frac{\partial F_2}{\partial \theta} \sin \theta$$

we transform the above expression into:

$$F_1^2 \sin^2 \theta' + (a' \cos \theta' + b' \sin \theta' \cos \phi)^2 + 2F_1(a' \cos \theta' + b' \sin \theta' \cos \phi) \sin \theta' \cos \phi.$$

Hence

$$\int_0^\pi \int_0^{2\pi} \int_0^{2\pi} r_1^{-2} \left[\left(\frac{\partial \psi}{\partial \theta_1} \right)^2 + (\sin \theta_1)^{-2} \left(\frac{\partial \psi}{\partial \phi_1} \right)^2 \right] \sin \theta' d\theta' d\phi' d\phi \\ = \frac{(4\pi)^2}{3r_1^2} [F_1^2 + (1/2)(a'^2 + b'^2) + b'F_1].$$

Using the symmetrical expression for the term in r_2^{-2} and replacing all integrals of $(a \cos \theta' + b \sin \theta' \cos \phi)^2$ by $(4\pi^2/6)(a^2 + b^2)$ equation (24) follows at once.

To verify (16) directly we evaluate

$$\frac{\partial^2 \psi}{\partial \theta_1^2} + \cot \theta_1 \frac{\partial \psi}{\partial \theta_1} + \frac{\partial^2 \psi}{\sin^2 \theta_1 \partial \phi_1^2}.$$

Remembering that

$$\left(\frac{\partial^2}{\partial \theta_1^2} + \cot \theta_1 \frac{\partial}{\partial \theta_1} + \frac{\partial^2}{\sin^2 \theta_1 \partial \phi_1^2} \right) \theta = \cot \theta$$

and the relation (a), the above expression reduces to

$$\cos \theta_1 \left[\frac{\partial^2 F_1}{\partial \theta^2} + 3 \cot \theta \frac{\partial F_1}{\partial \theta} - 2F_1 \right] - \cos \theta_2 \left[\frac{\partial^2 F_2}{\partial \theta^2} + \cot \theta \frac{\partial F_2}{\partial \theta} + \frac{2\partial F_1}{\sin \theta \partial \theta} \right]$$

similarly for

$$\frac{\partial^2}{\partial \theta_2^2} + \cot \theta_2 \frac{\partial}{\partial \theta_2} + \frac{\partial^2}{\sin^2 \theta_2 \partial \phi_2^2}.$$

Substituting into Schroedinger's equation, (16) follows on requiring independent vanishing of coefficients of $\cos \theta_1$, $\cos \theta_2$.

AN INTERPRETATION OF PAULI'S EXCLUSION PRINCIPLE

BY E. U. CONDON AND J. E. MACK*

UNIVERSITY OF MINNESOTA, MINNEAPOLIS

(Received February 6, 1930)

ABSTRACT

I. Pauli's exclusion principle can be understood as an instance of the subjectivity of our knowledge. We are built out of only a particular world constructed according to one of the non-combining patterns possible under the laws of quantum mechanics. Therefore we are capable of having sense perceptions of only that world.

II. Dirac's theory of the proton shows why Pauli's principle governs the world.

I.

PROBABLY the most important trend in current physics is that toward the recognition of the fact that our science gives no information about an objective reality wholly independent of ourselves. We are becoming increasingly impressed by the subjectivity of our knowledge. We owe much of this to the work of Bridgman with his emphasis on the unprofitableness of dallying over meaningless questions and his operational formulation of the reality of physical concepts. The rôle played by our subjective limitations on observation of the world about us has been discussed in detail by Heisenberg and by Bohr. We refer to the train of ideas known as Heisenberg's uncertainty principle.

Let us consider what the uncertainty principle did for physics. It came after the fairly complete formulation of the laws of quantum mechanics as we know them to-day. Before the principle the laws were quite definitely stated by Heisenberg, Born, Dirac, Jordan, Schrödinger, Pauli and others. They were stated so definitely that the method of treating special problems was recognised and applied with a good deal of success by a large number of physicists. Therefore, they were valid laws of science, since they met the test of being workable in the hands of physicists in general, and did not rest purely on the genius of the individuals who discovered them. Even without the principle they probably could have attained a universal applicability but we cannot say how that would have been, since, owing to the slowness of diffusion of scientific knowledge, the formal laws were still in the process of becoming the common property of professional physicists when Heisenberg enunciated the principle.

But before he did, even among those who had found the new methods workable and who had contributed to the many successes of the theory, there was a feeling of dissatisfaction, a feeling that the new theory was not understood, perhaps even not understandable. These were disturbing times for we

* National Research Fellow.

did not know why we felt dissatisfied (or perhaps unsatisfied) and so were quite helpless in attempting to remedy the situation. The remedy was provided by Heisenberg in his uncertainty principle. In a sense his famous paper in *Zeitschrift für Physik*, volume 43, has nothing new in it. For it does not alter or add to the formal statement of the laws of quantum mechanics. Nor does it apply them to any specific problem and produce calculations about some aspect of nature which are triumphantly in agreement with somebody's quantitative measurements. What it did do was to relieve that feeling of dissatisfaction. Many a physicist who had been working with the formalism of quantum mechanics felt that he understood it for the first time after he read that paper. Subsequently this satisfaction of understanding was considerably enhanced by the appearance of Bohr's Como lecture simultaneously in *Nature* and *Die Naturwissenschaften*. The title of Heisenberg's paper is significant: he called it the "anschaulich Inhalt" of the new quantum mechanics. It was just that: it was the intuitive, clear, evident content of the theory.

The important feature of this clear and intuitive part of the theory is the deflation of the lords-of-creation attitude of physicists. Wholly rational, detached fellows we thought ourselves (in our naive way), studying objectively the true laws of the external world. We had no concern with unfruitful stuff like metaphysics. Now we know otherwise and are healthily aware of our own organic relation to the traditionally inorganic subject matter of our science.

At present there is another law of nature (empirical, like all laws of nature) intimately connected with quantum mechanics, which we feel that we do not understand. This is Pauli's exclusion principle. We refer to the same feeling of dissatisfaction which was felt about quantum mechanics in general before Heisenberg's paper.

Pauli's principle grew out of empirical spectroscopy and was stated in the form that no two electrons in an atom can have the same set of quantum numbers. A formal place was found for this in the equations of quantum mechanics by Heisenberg, Dirac, Wigner and others. The equations of quantum mechanics showed a remarkable property when applied to the description of a dynamical system consisting of several dynamically similar particles. Such properties are naturally of fundamental importance because of the belief that all electrons are dynamically similar and that they are the fundamental stuff of which all substance is built. This remarkable property may be described by saying that such dynamical systems may exist in $N!$ different classes of states such that if the system exists now in one of these classes then it must exist for all time to come in this same class of states. (N is the number of similar particles in the system.) In other words, quantum mechanics provides, when applied to the dynamical system which is the entire universe, not just one solution but $N!$ possible solutions, which we may call worlds, where N is the total number of electrons in the universe. Since it is an exact conclusion from the postulated exact similarity of all the particles that the universe cannot change from one of these classes of states to

another, our universe must represent a selection from among these possible worlds. Which one? There is one which has the property that it has no possible states characterized by two of the particles' having the same quantum numbers. That one agrees with the world that we know.

That is fine but it leaves us with a lack of understanding of the matter which is, perhaps, akin to the unsatisfied feeling toward quantum mechanics which preceded the discovery of its "anschaulich Inhalt" by Heisenberg. What of the other $N!-1$ possible worlds?

Now we come to our main thesis: The restriction to a world built in accordance with Pauli's principle can be understood as another and extreme instance of the subjectivity of our knowledge. We, physicists, humans, are creatures who are built out of, and therefore are capable of reacting with and having sense perceptions of, only a particular world constructed according to a particular one of the non-combining patterns possible under the laws of quantum mechanics. Because of our own nature we are aware of, or conscious of, only that part of possible reality that is built on our pattern.

Do worlds really exist that are built (of the same electrons as ours) on one of the other patterns but nevertheless according to the laws of quantum mechanics? The question is meaningless in a sense because of our subjective incapacity to be aware of them. It is meaningless for the same reason as is the question, (sometimes asked after an individual has heard, for the first time, an exposition of Heisenberg's uncertainty principle) "Does a particle really have precise position and momentum simultaneously even though we cannot be experimentally aware of precise values for them?"

The situation turns on the meaning to be ascribed to the word "really" in the two questions. We prefer to associate with it the connotation, within the power of human sense perceptions. In that case the answer to both of them is no, as the "even though" clause makes ridiculously self-evident in the case of the second one. But we are reluctant to dismiss the other possible worlds quite so readily as we do simultaneous position and momentum. This is because the other worlds correspond to solutions of the equations of quantum mechanics, whereas there is no place in the structure of the mathematical formalism of quantum mechanics for simultaneous exact position and momentum.

Objective reality these other worlds cannot have, because of our subjective inability to react to them. (Remember that all objective reality is colored by important subjective elements!) This we feel is the simple, evident substratum of the Pauli exclusion principle which provides us with the right to say we "understand" it.

II

The foregoing shows that we can be conscious of only one of the possible worlds. But it throws no light on a possible reason why the real one is the one which obeys Pauli's exclusion principle.

One feels that the type of symmetry represented in our world is especially simple and that there must be some reason for it. It is another instance of an

ancient paradox: out of $N!$ possibilities the chance of the Pauli principle world being the real one seems vanishingly small. But in the matter of building the real world the dice are cast but once and in that one throw the antisymmetric pattern has an equal chance with the others.

Dirac's recent theory of the proton published in the Proceedings of the Royal Society for January, 1930, throws new light on the matter, however. When we spoke in *I* of there being $N!$ different possible worlds according to quantum mechanics, we were speaking of the non-relativistic theory. But the relativistic theory of the electron must represent a surer foundation on which to build cosmologic hypotheses. According to it, electrons can exist in states of negative energy (less than $-mc^2$), as well as in usual states of positive energy (of the order $+mc^2$). We have no experimental evidence of electrons of this sort and so the prediction of such negative energy electrons was regarded as a blemish in the theory. But now the solution to the difficulty is seen in the fact that Pauli's principle governs our world.

We can do no better than quote the crucial paragraph of Dirac's paper:

"The most stable states for an electron (i.e. the states of lowest energy) are those with negative energy and very high velocity. All the electrons in the world will tend to fall into these states with emission of radiation. The Pauli exclusion principle, however, will come into play and prevent more than one electron going into any one state. Let us assume that there are so many electrons in the world that all the most stable states are occupied, or, more accurately, that *all the states of negative energy are occupied except perhaps a few of small velocity*. Any electrons with positive energy will now have very little chance of jumping into negative-energy states and will therefore behave like electrons are observed to behave in the laboratory. We shall have an infinite number of electrons in negative-energy states, and indeed an infinite number per unit volume all over the world, but if their distribution is exactly uniform we should expect them to be completely unobservable. Only the small departures from exact uniformity, brought about by some of the negative-energy states being unoccupied, can we hope to observe."

And now we see why it is that the Pauli principle world is the only one which can be built out of Dirac's relativistic electrons. For it is the only one in which the available states can be filled up. For the others there is no limit to the number of electrons that can occupy a state. The antisymmetric one is the only pattern that has a "bottom." For the others all the electrons in the universe would be drained off into states of indefinitely great negative energy.

THE X-RAY SCATTERING POWERS OF NICKEL
AND OXYGEN IN NICKEL OXIDE

BY RALPH W. G. WYCKOFF

ROCKEFELLER INSTITUTE FOR MEDICAL RESEARCH, NEW YORK CITY

(Received February 6, 1930)

ABSTRACT

Atomic F -curves for the nickel and oxygen atoms in NiO have been obtained from measurements of the intensities of the principal powder reflections of molybdenum, copper and nickel $K\alpha$ radiations. Though the scattering power of oxygen remains nearly constant with respect to NaCl for these wave-lengths, that of nickel shows important variations.

THIS paper forms part of a series of studies of the dependence of the diffracting power of an atom upon the wave-length of the x-rays being scattered. Accurate measurement¹ has shown that with wave-lengths as near together as the $K\alpha$ lines of molybdenum and rhodium the F -values of NaCl are equal for the same $\sin \theta/\lambda$. There is likewise some indication² that the atoms in this crystal do not have very different scattering powers for copper radiation. Recent comparisons of NaCl and metallic silicon³ prove that the ratio of their diffracting powers is nearly the same for molybdenum and for copper $K\alpha$ x-rays. All of these observations are with radiations far removed in frequency from any critical values for the diffracting atoms.

Such a parallelism as that prevailing between NaCl and silicon no longer seems to hold if the comparisons involve metallic copper and iron reflecting molybdenum and copper rays. The experiments already made⁴ with these metals indicate that their scattering powers decrease more rapidly with increasing wave-length than do those of the atoms of NaCl. This conclusion is dependent upon the essential correctness of measured absorption coefficients.

Observations upon NiO avoid such an uncertainty by containing within themselves a comparison of the scattering powers of two atoms—nickel and oxygen. These data consist of determinations of the F -curves of nickel and oxygen using molybdenum, copper and nickel $K\alpha$ radiation. The measurements upon which they are based are spectrometer studies of the intensities of the principal x-ray reflections of powdered NiO. The methods used in obtaining these intensities⁵ and reducing them to atomic scattering powers have been described.

Two different samples of chemically pure green NiO gave results which were identical within the limit of experimental error. In order to suppress the effects of extinction both crystal powders were ground thoroughly in an agate mortar and passed through a 325 mesh per linear inch sieve before being formed into a cake.

Molybdenum radiation was obtained from a water-cooled General Electric tube operated from a synchronous motor-generator-kenetron-condenser

set at 30 kv with a current consumption of 5 or 10 ma. The copper and nickel radiations were supplied by Siemens-Phoenix tubes passing 6 ma at 25 kv. The molybdenum rays were rendered essentially monochromatic with a ZrO_2 screen. No attempt was made to filter the x-rays emitted by the copper and nickel target tubes but calculation showed that with the resolution used none of the measured $K\alpha$ spectra was contaminated by other reflections.

TABLE II. *The F -values of powder reflections of nickel oxide.*

Indices	$\sin \theta/\lambda$	$F(Mo K\alpha)$	$F(Cu K\alpha)$	$F(Ni K\alpha)$
111	0.2076	14.13	11.41	13.01

400	.4796	13.65	10.12	—
133	.5223	9.22	—	—
240	.5359	11.65	—	—
224	.5871	10.96	—	—
333,115	.6229	7.96	—	—

The crystal structure of NiO is identical with that of NaCl. Reflections with odd indices therefore represent differences between the contributions of nickel and oxygen atoms, those with even indices (all even order spectra) are due to the cooperation of these two atoms. The relative intensities of the observed reflections for Ni $K\alpha$, Cu $K\alpha$ and Mo $K\alpha$ rays are shown in Table I.

The absolute F -values for molybdenum radiation have been found by comparing the (200) reflection of NiO with (220) of NaCl. A mean of several

determinations using both samples of NiO gave $(200)\text{NiO}:(220)\text{NaCl}=49.6:100$. The apparent accuracy of this ratio is better than 5 percent. The mass absorption coefficient of NiO according to the experiments of Windgardh⁶ is $\mu/\rho=37.93$. If Allen's⁷ value for nickel is used, μ/ρ becomes 37.21. The absorption coefficient of NaCl as provided by Windgardh's data is $\mu=18.21$ ($\rho=2.16$). Of the other quantities⁸ needed to calculate absolute F 's, ρ has been taken as 6.75, $a_0(\text{NiO})=4.17\text{\AA}$, $a_0(\text{NaCl})=5.628\text{\AA}$, $F(220, \text{NaCl})=15.62$. Introduction of these values into the customary expressions leads to the reflection F 's recorded in Table II and Fig. 1. Points on the smooth F -curves drawn through them, when separated by addition and subtraction into

Fig. 1. The reflection F -values observed from NiO using molybdenum, copper and nickel $K\alpha$ radiations.

atomic F -values for nickel and oxygen, give the numbers listed in Tables III and IV and plotted in Fig. 2.

In order to place the F -curves for copper and nickel radiation upon an "absolute" scale for comparison with those for molybdenum x-rays, it has been assumed that $F(220, \text{NaCl})=15.62$ for all three radiations. The absorption coefficients for NiO as calculated by Jönsson's formula⁹ are $\mu=276.8$ for $\text{Cu } K\alpha$ and $\mu=345.1$ for $\text{Ni } K\alpha$. They are in good agreement with existing experimental values. Absorption coefficients for NaCl obtained in the same way are $\mu=161.2$ for $\text{Cu } K\alpha$ and $\mu=196.2$ for $\text{Ni } K\alpha$. Measurements of the

Note: Values in parentheses in this and the following table are obtained by extrapolating the Ni-O curve of Fig. 1.

A check upon the accuracy of the measurements of this paper can be had by comparing the oxygen F -curves for Mo $K\alpha$ from NiO and¹⁰ MgO. Though

¹⁰ R. W. G. Wyckoff and A. H. Armstrong, Zeits. f. Krist. **72**, 433 (1930).

it is scarcely to be expected that they should be identical, these two curves ought to lie close to one another (Fig. 3).

The most significant feature of these results is the fact that though the oxygen F -curves are nearly identical for the three radiations—or, more accurately, vary in the same manner as does NaCl—relatively large differences exist in the curves for the nickel atoms. Since critical wave-lengths of oxygen

length as this critical range is approached. The greater diffraction of nickel for the nickel than for the copper $K\alpha$ line indicates that this downward trend is broken either some time before or when a wave-length characteristic of the scatterer is reached.

Further experiments are being made with various metals and with several wave-lengths which will bear upon these phenomena.

THE EFFECT OF HYPERFINE STRUCTURE DUE TO
NUCLEAR SPIN ON POLARIZATION OF
RESONANCE RADIATION

BY A. ELLETT

DEPARTMENT OF PHYSICS, UNIVERSITY OF IOWA

(Received February 6, 1930)

ABSTRACT

The existence of hyperfine structure must be taken into account in calculations of the polarization of resonance radiation based upon Heisenberg's extension of the principle of spectroscopic stability. Where the hyperfine structures are due to the existence of a nuclear moment their effect upon the polarization of resonance radiation may be calculated. If the nuclear moment of the thallium atom is $\frac{1}{2}$ (in units of $\hbar/2\pi$) as Schüler and Brück suppose the $\lambda\lambda 3776$ and 5350 lines should show no polarization, while $\lambda 2768$ should show 33.3 to 35.1 percent parallel and $\lambda 3530$ 41.8 to 48.8 percent perpendicular to the electric vector of a plane polarized exciting beam. Sodium resonance radiation excited by plane polarized D_1 and D_2 lines should show 33.3 percent polarization if the nuclear moment is $\frac{1}{2}$ and 16.6 percent if it is 1. The latter value agrees well with 16.3 observed by the writer, but observations on band spectra seem to indicate a higher nuclear moment, according to F. W. Loomis and R. S. Mulliken (Verbal communication to the writer.)

THE success of Back and Goudsmidt¹ in accounting for the hyperfine structure and Zeeman effect of the Bismuth arc spectrum by ascribing a mechanical and magnetic moment to the nucleus of the atom has led to attempts to explain hyperfine structure found in various other spectra in the same manner. Schüler and Brück² have shown that the hyperfine structures of the TII spectrum are probably due to a nuclear moment of $\frac{1}{2}$ (in units of $\hbar/2\pi$) and McLennan, McLay, and Crawford³ have shown that their observations on TI II lend support to this hypothesis. More recently Schüler and Brück⁴ have had some success in unraveling the hyperfine structures of Cd I by supposing that this spectrum is really two superimposed—one without hyperfine structure due to the cadmium isotopes of even atomic number which are supposed to have no nuclear moment, and another with structure due to a nuclear moment ascribed to the odd isotopes.⁵ The idea of nuclear spin has been used also by Jackson⁶ and by Hargreaves⁷ to account for Jackson's observations on the hyperfine structure of Cs I.

¹ Back and Goudsmidt, *Zeits. f. Physik* **43**, 321 (1927); **47**, 174 (1928). Pauli, *Naturwiss.* **12**, 741 (1924) suggested the idea of nuclear spin, but it was not successfully applied to the explanation of hyperfine structures until the paper of Back and Goudsmidt.

That the existence of hyperfine structures must be taken into account in any comparison of theory and experiment on the polarization of resonance radiation or of radiation excited by electron impact is obvious for the calculation of the polarization in the absence of a magnetic field, based on the idea of spectroscopic stability,⁸ involves the relative intensities of the Zeeman components of the line in *very weak* fields.

All previous calculations of the polarization of resonance radiation have been carried out without taking into account the existence of hyperfine structure. The Zeeman patterns and transition probabilities used have been those calculated for an atomic model without nuclear spin. These intensities are, at least to a first approximation, those which will obtain when the Paschen Back effect of the *hyperfine structure* is complete. There is no reason to expect that calculations made on this basis will show good agreement with experiment and in fact the agreement in general is poor. That hyperfine-structure is responsible for the 80 percent polarization of the $\lambda 2537$ A. U. resonance radiation of mercury has been shown experimentally by MacNair and the writer.⁹

It is not likely that the hyperfine structure of this line is to be accounted for on the hypothesis of nuclear spin alone but in the case of thallium and perhaps sodium the situation is different, and it is interesting to see whether taking into account the nuclear spin will lead to better agreement between theory and experiment.

The present calculations are based on the assumption that the coupling between i , J , and f is of the same character as that between L , S and J in alkali spectra. That is, it is supposed that i , the nuclear moment, combines vectorially with J , the net moment due to the remainder of the atom to give a resultant f in the same way that L and S combine to give a resultant J . This is the assumption used by Back and Goudsmidt¹ and by Schüler and Brück.^{2,4} The relative intensities of the hyperfine lines making up a hyperfine structure pattern (which itself appears as a 'line' save under high revolving power) may be calculated by formulas given by Hill¹⁰ and by Hargreaves.⁷ The relative intensities of the Zeeman components of the hyperfine lines may be calculated by the usual Kronig-Hönl formulas.¹¹ The polarization to be expected in any specified experiment is then calculated by making use of a consequence of the principle of spectroscopic stability first enunciated by Heisenberg.⁸ This extension of the principle of spectroscopic stability may be applied in any case where the experimental situation presents an axis of symmetry, and it states specifically that the introduction of a magnetic field parallel to this axis will not alter the relative probabilities of transitions giving rise to radiation polarized respectively parallel or perpendicular to this symmetry axis. The field is introduced merely to remove the degeneracy which exists in the absence of any field. That is, its purpose is to render

distinct the various magnetic energy levels which coalesce in the absence of a field so that the relative probabilities of transitions between these levels may be calculated. While this hypothetical field must be a strong field in the sense that the degeneracy is removed completely it must at the same time be a weak field so far as the production of Paschen Back effect of the hyperfine structure is concerned. The justification of such procedure then requires that the separation between the various hyperfine structure components of a line should be large compared to the intrinsic breadth of these components. This intrinsic breadth has nothing to do with the breadth of lines as observed in high resolving power spectroscopes; the latter is due to Doppler effect and pressure broadening (collisions) etc. We refer here to the inherent breadth of the line occasioned by imperfect definition of energy levels resulting from the finite life of stationary states.

To calculate the polarization of resonance radiation excited by plane polarized exciting light in the absence of a magnetic field we must imagine a field introduced, its direction being that of the symmetry axis (here the electric vector of the exciting light) so that we may calculate the relative numbers of transitions to the several Zeeman levels into which the upper states involved are split. Then having calculated the relative populations of these levels we determine the relative numbers of return transitions giving rise to radiation polarized parallel or perpendicular to the field. From this we get the polarization of the reemitted radiation and are assured that the value so calculated is that which will obtain when the field is removed.

THALLIUM

The thallium lines arise from transitions shown in the Grotrian diagram, Fig. 1a. Each of the levels shown is split into two when a nuclear moment of $\frac{1}{2}$ is taken into account, and these with the appropriate values of the fine quantum number f , and the permitted transitions are given in Figs. 1b and 2. The values of the transition probabilities are given by Hargreaves⁷—or

Fig. 1a. Grotrian diagram for thallium.

Fig. 1b. Permitted transitions in thallium.

they may be readily computed from the formulas given by Hill.⁹ From the figures it is evident that excitation by $\lambda 3776$ Å. U. will give rise to the emission of this line and also $\lambda 5350$ Å. U. while absorption of $\lambda 2768$ Å. U. excites $\lambda 5350$ Å. U. in addition to itself. In Fig. 2 are shown the Zeeman levels and

transitions involved in the emission of $\lambda\lambda 3776$ and 5350 A. U. Excitation by plane polarized light will excite atoms to those upper energy levels reached by those transitions of $\lambda 3776$ A. U. marked || (parallel) in the figure, the relative numbers of excited atoms in the various upper states depending upon the values of the parallel transitions reaching it and upon the intensity of the incident light of wave-length appropriate to produce these transitions. The question of relative intensities in the exciting radiation need not bother us here however, for no matter what the relative populations of the upper levels the reemitted radiation of each of the aggregates of hyperfine lines composing $\lambda\lambda 3776$ and 5350 A. U. will be unpolarized. That is to say, in each of these aggregates from *each* upper level the chance of returning by a perpen-

Fig. 2. Permitted transitions in thallium.

dicular transition is twice that of returning by a parallel transition. This leads to no net polarization either parallel or perpendicular to the electric vector of the exciting light—for parallel transitions produce such a distribution of the reemitted radiation as would be produced by a linear oscillator parallel to the electric vector of the exciting light (and also parallel to our imaginary magnetic field) while perpendicular transitions give rise to a distribution such as would be occasioned by a circular oscillator in a plane perpendicular to this.

Figure 3 shows the levels involved in absorption and emission of $\lambda\lambda 2768$ and 3530 A. U. Here the relative population of the upper levels is of some consequence and it becomes necessary to make some assumption regarding the distribution of intensity over the hyperfine structure components of

$\lambda 2768$ A. U. Two cases will be considered — A — that of uniform intensity over the entire absorption pattern, a situation perhaps realizable with a very hot source emitting greatly broadened lines, and — B — that of the theoretical intensity ratios,—such as might be realized with a source run at a temperature low enough so that Doppler broadening will cause no overlap of

Fig. 3. Levels involved in absorption and emission of $\lambda\lambda 2768$ and 3530 .

hyperfine structure components, and with the density of thallium vapor low enough to eliminate self reversal. In column A of Fig. 3 are given the relative populations of the upper levels for case A and in column B for case B. Table I summarizes the results for these four lines.

TABLE I.

thallium as well as cadmium⁴ there is a difference of nuclear moments of the isotopes. The presence of an isotope having zero nuclear moment would result in higher values for the polarization, but the presence of such an isotope is not indicated by the spectroscopic data. An isotope with nuclear moment greater than one half probably would lead to even lower values of the expected polarization as a higher nuclear moment means an increased multiplicity of hyperfine structure levels. This might be offset by the changed intensity distribution in the exciting light, as it would be to some extent at least if the components of the hyperfine structure pattern responsible for the polarization should have the same wave-length in the patterns of both isotopes. Whether such a situation exists we cannot say without a more detailed spectroscopic analysis of the thallium hyperfine structures.

SODIUM

For a sodium atom without nuclear moment resonance radiation excited by the D_2 line alone should be 60 percent polarized. When excited by D_1 and D_2 together, using a source such that the effective intensity ratio of the two lines is 2:1 (the theoretical value) the predicted polarization is 50 percent. In 1925 the writer found¹⁴ 16.3 percent for the polarization of resonance radiation excited by both D lines, which corresponds to a value of 20.1 percent for D_2 alone not 24 percent as Datta states.¹⁵ Datta, exciting by means D_2 alone got values as high as 33 percent with the resonating vapor in equilibrium with metallic sodium at 115°C. He supposed that the lower value obtained by the writer was due to higher vapor pressure. This however is not the explanation, for the vapor pressure was actually less than the lowest at which Datta made observations; 95°C and $7.4 \cdot 10^{-8}$ mm. Hg¹⁶ as against his values of 115°C and $4.5 \cdot 10^{-7}$ mm Hg. More recently the experiment has been repeated with a somewhat more powerful source and vapor pressures as low as $1.9 \cdot 10^{-8}$ mm Hg (80°C). The polarization was again found to be 16.3 percent. The reason for the difference between this value and Datta's is not obvious to the writer.

Schüler¹⁷ has observed hyperfine structure of the D lines, and as the hyperfine structure observed in caesium appears to be due to a nuclear moment, I have calculated the polarization to be expected in D line resonance radiation on the assumption of various nuclear moments. In every case the value is less than it is for the atom without nuclear moment. As the sodium hyperfine structure is on a very small scale it has been assumed that the intensity of the exciting light is uniform across the hyperfine structure pattern. This amounts to supposing that the separations in the pattern are small compared to the Doppler line breadth at the temperature of the source. The temperature of the glass walls of the source used by the writer was about 750°C and

¹⁴ Ellett, Jour. Opt. Soc. Am. 10, 427 (1925).

¹⁵ Datta, Zeits. f. Physik, 37, 625 (1926).

¹⁷ Schüler, Naturwiss. 16, 512 (1928).

the emission lines have a corresponding breadth, as I have shown by experiments on polarization of resonance radiation in strong magnetic fields.¹⁸

The results of these calculations are summarized in Table II.

TABLE II.

i	0	1/2	1	obs.
D_2	60	40.54	20.5	33 ¹⁴
D_1	0	0	00	00
D_1+D_2	50	33.3	16.6	16.3 ³

In this connection it should be mentioned that observations of alternating intensities in sodium band spectra indicate a quite large nuclear moment,¹⁸ probably greater than one, which probably would lead to even lower values for the polarization.

In conclusion it may be said the presence of hyperfine structure due to nuclear spin cannot be neglected in calculating the polarization of resonance radiation and radiation excited by electron impact. Taking account of such hyperfine structures in certain thallium and sodium lines leads to lower values of the predicted polarization and consequently better agreement between theory and experiment. Experiments on the polarization of resonance radiation may yield the data required for the solution of hyperfine structure problems in cases where direct spectroscopic analysis is impossible, as in the case of overlapping of certain components in the hyperfine structure patterns because of Doppler breadth of the lines.

¹⁸ F. W. Loomis and R. S. Mulliken agree from inspection of Loomis spectrograms of Na₂ bands that i is probably 3/2 or greater. (Verbal statement to the writer). See also Loomis and Wood, Phys. Rev. 32, 223 (1928).

SPECTROSCOPIC EVIDENCE OF TWO TYPES
OF AMMONIA MOLECULE

BY JOSEPH W. ELLIS

PHYSICS DEPARTMENT, UNIVERSITY OF CALIFORNIA AT LOS ANGELES

(Received February 3, 1930)

ABSTRACT

A two-fold difference exists in the equations expressing the anharmonic frequencies arising from vibratory energy changes in ammonia molecules in solution and in gaseous form. The greater coefficient of the n^2 term in the former case, indicating a more rapid approach of the energy terms toward confluence, is assumed to arise from the proximity of the molecules of the solvent. The presence of a constant term of appreciable magnitude in the solution equation is interpreted as measuring the energy required to change the molecule from an α form to a β form of greater potential energy. Chemical support for this latter interpretation is sought in some earlier measurements by Baly and Duncan on the difference in the decomposition rates of ammonia both after immediate evaporation from the liquid and after it had stood for a considerable length of time.

It becomes easier to interpret the Raman spectrum of liquid ammonia, ammonia in aqueous solution and a liquid organic derivative of ammonia, aniline, when the existence of a constant in the infra-red formula is recognized.

BADGER and Mecke¹ and the author² have independently come to the conclusion that the ammonia molecule has a fundamental absorption wavelength near 3μ . This conclusion has been arrived at in each instance by the discovery that there is an anharmonic series of absorption bands with members in the infra-red spectrum below 3μ and in the visible spectrum. The former investigators have photographed the fourth and fifth members of this series in the visible region, using long tubes of gaseous ammonia and a concave diffraction grating to secure high dispersion and resolving power. Out of the complex structure caused by rotational quantum changes they have been able to pick the lines produced by vibrational energy changes alone. They have sought the second and third members in the thermal measurements of Robertson and Fox³ and have used the frequency values of the centers of these unresolved bands. For the first member they have chosen the frequency of maximum absorption in the unresolved Q branch in the record given by Barker.⁴ They have shown that these five frequencies can be fairly well fitted to the following anharmonic formula:

$$\nu_n = 3396n - 60n^2. \quad (1)$$

The author² has used a quartz prism spectrograph to photograph the structureless absorption bands corresponding to the fourth and fifth series

¹ Badger and Mecke, *Zeits. f. Phys. Chem. B* 5, 333 (1929).

² Ellis, *Journal Franklin Inst.* 208, 507 (1929).

³ Robertson and Fox, *Proc. Roy. Soc. A* 120, 128 (1928).

⁴ Barker, *Phys. Rev.* 33, 684 (1929).

members caused by ammonia in aqueous solution. In a similar manner he has also found the weak sixth member in the visible green spectrum. Records of the second and third members have been secured by means of a registering infra-red spectrograph equipped with a thermopile. These latter he has shown retain their positions when carbon tetrachloride replaces water as a solvent. No data for the solution were then available for the first member. For reasons explained in the above reference a wave-length value of 2.916μ was assigned to the initial member of the series.

Although the former reason for selecting this value does not now seem to be well founded, the wave-length value chosen has been shown to be at least approximately correct. To show this a Hilger D 35 infra-red spectrometer equipped with a rock-salt prism was used. A 1 cm cell of ammonia in carbon tetrachloride solution was placed before the slit of the instrument and observations were made on the 3μ region. The difficulty experienced by Robertson and Fox³, namely that the wave-length determination of an absorption maximum is influenced by the variations in the refractive index of the rock-salt prism caused by temperature changes, was experienced here. When, for example, the wave-drum was set for a correct reading with the yellow sodium lines filling the thermopile slit and the instrument allowed to stand for a while with the lamp source radiating near by, the absorption band produced by a 1 mm cell of benzene shifted from its true position of 3.27μ to a value in excess of 3.4μ . Consequently, just prior to a determination of the position of the ammonia band, the reflecting mirror near the prism was so adjusted that when the galvanometer showed a minimum deflection, indicating that the maximum of absorption due to the benzene had been reached, the wave-drum indicated 3.27μ . With this procedure it was found that the ammonia solution band was not at 3.0μ , the position occupied by the gaseous ammonia band, but at 2.9μ .

The frequencies of the six members of the series observed in solution have been shown² accurately to fit the formula:

$$\nu_n = 97 + 3400n - 70n^2. \quad (2)$$

Now in spite of the assertion by Mecke⁵ that there is a good agreement between the bands observed in gaseous ammonia and in solution, a closer examination reveals a significant difference. This difference is two-fold and is revealed in Eq. (2) by the presence of the constant term 97 and by the larger coefficient of the n^2 term, 70 as compared with 60 in Eq. (1). The presence of the constant term arises from the origination of the solution series at 2.9μ rather than at 3μ . The greater coefficient of the quadratic term explains why in the higher series members the wave-lengths of the solution bands become greater than the corresponding bands in the gas. This earlier confluence of the solution series must arise from a more rapid diminution of the force coefficient of the vibrator caused by the proximity of surrounding molecules. In general, however, a less rapid approach of the series members toward confluence would be expected, because this would

⁵ Mecke, Trans. Faraday Soc. 25, 942 (1929).

mean a lesser value for the heat of dissociation of the vibrator. And heats of dissociation evaluated from data obtained from the liquid state should be less than heats of dissociation evaluated from the gaseous state by an amount approximately equal to the heat of vaporization.

Fig. 1 is included to show the difference in the locations of the fifth members of the series in solution and in the gas. The figure shows the solution band approximately symmetrically located between two neon comparison lines, 0.6507μ and 0.6533μ . It has been given the value of 0.652μ . The value given by Mecke and Badger for the analogous gaseous band is 0.647μ , which lies completely outside of the region of absorption in the solution.

The constant term in Eq. (2) has been interpreted² as representing the amount of energy, in wave-number units, required to change the molecule in solution over to a new form before vibration takes place. A chemical investigation carried out a number of years ago by Baly and Duncan⁶ seems to have some bearing upon this subject. These authors showed that

Fig. 1. The 0.652μ absorption band of ammonia in aqueous solution.

ammonia gas which had been slowly evaporated from the liquid or which had stood for some time in contact with the liquid had a certain constant rate of decomposition. The decomposition was effected by thermal energy supplied at a known rate by a heated platinum wire and the decomposition rate was determined from pressure changes in the gas. But when the experiment was repeated upon gas which had been suddenly evaporated from the liquid they found that the decomposition rate was much less than in the previous instance. Furthermore, this rate gradually increased with time. These facts led the investigators to postulate two forms of ammonia molecules, which they designated inactive and active forms, but which we shall designate as α and β forms respectively for reasons which will be apparent presently. The molecules are in the α form when the substance is in the liquid state or in the gaseous state immediately following sudden vaporization. The β form makes up predominantly, or exclusively, the gas which has stood

⁶ Baly and Duncan, Jour. Chem. Soc. **121**, 1008 (1922).

for a considerable length of time. According to these investigators, the decomposition rate of inactive (α) ammonia is lessened because of the use of a portion of the energy supplied by the wire to activate the molecules.

Tronstad⁷ has pointed out that the experimental procedure of Baly and Duncan was similar to that of Bonhoeffer and Harteck in their study of ortho and para hydrogen. He furthermore has stated that Baly and Duncan have not proved the existence of two chemically different types of ammonia molecules, but that their results can be explained equally well on the basis of two forms with different heat conductivities and specific heats. The two types would then be analogous respectively to para and ortho hydrogen.

From considerations of the experimental results of Baly and Duncan it may be concluded that the 97 cm^{-1} term of Eq. (2) represents an energy of "activation." (The assumption is made here that ammonia in solution exists in the α state.) However, in the light of Tronstad's criticism it must be recognized that this activating process may be one in which geometrical and physical changes occur rather than chemical changes.

From the quantitative measurements of Baly and Duncan it would seem that the modified interpretation of Tronstad is the more tenable. Baly and Duncan have shown that in some instances the amount of decomposition is doubled when the β form is used in place of the α form. Under their interpretation then half of the energy supplied by the hot platinum wire must go into energy of activation. Now the energy required to decompose one molecule of NH_3 into NH_2 and H requires some $30,000\text{--}40,000\text{ cm}^{-1}$ which is 300 or 400 times as great as the 97 cm^{-1} energy of activation. But Baly and Duncan state that from 0.5 to 4 percent of the molecules are decomposed during the 20 seconds of observation; and under the assumption that this percentage of molecules decomposes, say into NH_2 and H, there would be required many more molecules than the total number available, to take up the energy of activation.

Following Tronstad's assumption of a greater heat conductivity characterizing the α molecules, the difficulty met with in the discussion of the above paragraph does not enter, for more of the heat than previously could escape to the surrounding constant temperature water bath.

It should be pointed out that Barker,⁸ following Hund, has postulated two forms of ammonia molecule in his interpretation of the doubleness of another fundamental infra-red band of ammonia at 10.5μ . The difference in potential energy between the two types, however, is only 27 cm^{-1} . The approximate equality in intensity of the two components of this double band lead to the conclusion that the two kinds of molecules postulated must exist in the gaseous state with approximately equal abundance. Mecke⁹ also believes that his visible bands which are harmonics of the 3μ fundamental also exhibit a double structure, one set being much weaker than the other. But the frequency difference which he finds is even lower than Barker's 27 cm^{-1} .

⁷ Tronstad, *Zeits. f. Phys. Chem. B* 5, 333 (1929).

⁸ Barker, *Phys. Rev.* 33, 684 (1929).

⁹ Mecke, *Phys. Zeits.* 30, 907 (1929).

The Raman spectrum of ammonia exhibits one, two or three lines corresponding to the 3μ region, the exact locations and number of components depending upon the phase in which the substance exists and upon the individual investigators. Wood¹⁰ and Dickinson, Dillon and Rasetti¹¹ have shown that the Raman frequency corresponding to a rotationless vibrational energy change in the gaseous molecule is 3330 and 3334 cm^{-1} respectively, in good agreement with the 3336 cm^{-1} value obtained by putting n equal to 1 in Eq. (1). The latter investigators¹¹ have shown that liquid ammonia yields two frequencies, 3298 and 3214 cm^{-1} . Daure,¹² however, found in addition to these two frequencies, a third one at 3380 cm^{-1} . His record shows that all three components have approximately equal intensities.

Carrelli, Pringsheim and Rosen¹³ found two frequencies, 3385 and 3312 cm^{-1} , when they used an aqueous solution of ammonia. These authors recognized, however, the possibility that one of these components may have been due to the water solvent.

If the three components found by Daure in the liquid all originate in ammonia molecules, they might be explained by assuming the existence of both the α and β forms of molecule in the liquid state. The components corresponding to greatest, intermediate and least frequency changes could then be correlated with the following energy changes respectively:— α , $0 \rightarrow \beta$, 1; α , $0 \rightarrow \alpha$, 1 or β , $0 \rightarrow \beta$, 1; and β , $0 \rightarrow \alpha$, 1. Here α , 0 designates a vibrationless α type of molecule, β , 1 a β type of molecule vibrating in quantum state 1, etc. The 80 and 90 cm^{-1} frequency differences between the components are comparable to the 97 cm^{-1} term of Eq. (2). However, the failure of Dickinson, Dillon and Rasetti completely to corroborate the findings of Daure raises the question as to whether impurities may have been present in the latter's experiment. Water would be the most likely impurity and water yields at least two Raman bands with frequencies comparable to those given.

Spectroscopically, aniline, $\text{C}_6\text{H}_5\cdot\text{NH}_2$, which is a derivative of ammonia, behaves in a manner similar to its parent substance. The writer has justified his earlier correction¹⁴ to Bell's¹⁵ 2.8μ value for the fundamental N-H band, for he has studied the 3μ region for aniline with the Hilger D35 infra-red spectrometer and has found the band to have its maximum of absorption at 2.9μ . There is a remarkably close agreement between the members of the anharmonic series originating at 2.9μ for aniline and for ammonia in solution. Consequently, a constant term must be included in the aniline series, a fact which has hitherto¹⁴ been overlooked.

Again, the Raman effect in aniline according to Bonino¹⁶ shows a single frequency shift corresponding to a 3.0μ wave-length, rather than to 2.9μ . Thus once more the difference between the Raman frequency and the fundamental infra-red frequency is of the order of 97 cm^{-1} .

THE AFTERGLOW IN AIR

BY JOSEPH KAPLAN

UNIVERSITY OF CALIFORNIA AT LOS ANGELES

(Received January 6, 1930)

ABSTRACT

It was observed that on passing a weak discharge through the air glow the β bands of nitric oxide were very strongly excited. These bands possess several very interesting properties. They correspond to a transition from the B to the X level of the molecule and the transition B_0-X_0 is very improbable because of the large difference in nuclear separation. These bands have never been reported as being intense in electric discharges and they have been obtained with considerable intensity only in active nitrogen. This present experiment is therefore the first one in which these bands have been observed with great intensity in an electric discharge. The β bands, as observed in the present experiments, correspond to transitions only from the B_0 to the various X vibrational levels, whereas in the afterglow of active nitrogen they correspond to transitions from several B levels to the various X levels. This difference indicates that there are at least two possible methods for exciting these unusual bands and they have been discussed in brief by Kinsey and the author. They are excitation by recombination, and excitation by collisions of the second kind.

INTRODUCTION

THE problem of afterglows has been attacked in a great many different ways in recent years. Of the various afterglows that have been studied the one receiving the most attention has been the afterglow in active nitrogen. The reason for the widespread interest in active nitrogen is readily understood when one considers the many interesting phenomena that have been observed in connection with it. These extend from the field of excitation of spectra by active nitrogen to that of surface chemistry. And because of the large range of action of active nitrogen it has been interesting both as a tool and as a problem in itself. In the present communication it is proposed to discuss some aspects of a much less studied and apparently far less interesting afterglow. The afterglow referred to is the one that is observed when almost any type of discharge is passed through air at pressures around 0.5 mm.

This afterglow was first observed by E. P. Lewis¹ and also studied by R. J. Strutt² during those years in which he made many very valuable contributions to the problem of afterglows. The spectrum of the air glow has not been studied to any great extent and there are no published photographs of it. Herzberg,³ and independently the author,⁴ have photographed the spectrum of the glow and found it to be continuous. Herzberg has reported a

maximum in the red and a decrease of intensity toward the violet. In addition to the continuous spectrum in the visible, the writer has reported the excitation of the OH band at 3064Å. This band was undoubtedly excited by the active species in the afterglow, but as yet there is no basis for definitely discussing the process of excitation, since no experimental or theoretical work regarding the energy of the active species has appeared. Part of the purpose of the present work was to begin experiments designed for the purpose of studying in more detail than has been done, the nature of this afterglow.

Recently, Herzberg³ and others have revived interest in the air glow by applying to its study a few of the methods that had been used in connection with the nitrogen afterglow. Herzberg has studied the effect of varying the relative amounts of oxygen and nitrogen in the discharge in which the afterglow was produced and also the influence of the condition of the walls of the containing-vessel. Other papers by Majewska,⁵ Majewska and Witold⁶ and Bernard Lewis⁷ report work on the effect of surfaces, the rate of decay of the afterglow and on the mutual effects of nitrogen and oxygen on their afterglows. As the last title suggests, the continuous afterglow in air and in other mixtures of oxygen and nitrogen, has been ascribed to oxygen and several recent writers have suggested that it may simply be a recombination spectrum of atomic oxygen. It is not the purpose of this paper to discuss this point and it will be left for another communication. There is however no conclusive evidence in favor of the recombination hypothesis although the continuous spectrum makes that hypothesis a tempting one.

Another method of attack has recently been applied to the air afterglow by the author. The method, briefly, consists of allowing the active material to pass from the discharge in which it was formed into another discharge through which a very feeble current from a small spark coil is passing. The spectrum in the auxiliary tube is studied and the effect of the active material is noted. Recently Bay and Steiner⁸ have applied this method to active hydrogen, active nitrogen and to a modification of oxygen to which they refer as active oxygen. They used external electrodes and electrodeless ring discharges whereas in the present experiments internal electrodes were used. The method was first used by the author in an attempt to excite atomic nitrogen lines in active nitrogen and it yielded some very interesting results. In the following a brief account will be given of some of the results of the present work.

EXPERIMENTAL METHOD

The afterglow was produced by passing an uncondensed discharge from a 1 kw Thordarsson transformer, giving 20,000 volts in the secondary, through various mixtures of oxygen and nitrogen. The pressure of the gas in the discharge was 0.5 mm and this has been found to be the best pressure

for the production of the afterglow. It is interesting to note that 0.5 mm is also about the optimum pressure for the production of atomic hydrogen and active nitrogen. The active material was allowed to pass into another discharge tube, having internal electrodes, and a weak discharge from a small spark coil was allowed to pass through this tube. The spectrum of this discharge was photographed on a Hilger E2 spectrograph and also on a small Gaertner instrument. The auxiliary discharge was sufficiently weak as to make it necessary to expose for about ten hours on the Hilger instrument in order to obtain reasonably intense plates. It is apparently the weakness of the auxiliary discharge that makes the method a valuable one in the study of active materials from discharges.

EXPERIMENTAL RESULTS

Several interesting results were obtained but the only one that is to be here discussed is the excitation of the β bands of nitric oxide. A preliminary note on these results was published in the letter column of the *Physical Review*.⁹ The excitation of these bands with considerable intensity was certainly the most striking effect of the introduction of the active material into the weak discharge. The β bands are of special interest first because they have been obtained with considerable intensity only in the nitrogen afterglow and secondly, because of the large change in moment of inertia between the two levels that are involved in the excitation of these bands.

The β bands were first obtained by E. P. Lewis¹⁰ in active nitrogen. The present experiments are the first ones in which these bands have been excited with great intensity in an electrical discharge. Furthermore, these seem to be the first spectroscopic results, other than the continuous spectrum that was discussed earlier, that have been gotten from the air glow. In what is to follow, the origin of the β bands will be discussed and several questions of interest will be raised.

DISCUSSION

The β bands correspond to the transition from the B level to the X electronic level of the molecule. The X level is the normal level and both the B and X levels are now thought to be $^2\Pi$ levels. Although there will be no occasion in this discussion to refer to the electronic configuration of the two levels involved the older method of identifying the two levels will not be used and they will be referred to as the $^2\Pi$ levels. It is proposed here also to use v instead of n for the vibrational quantum number in accordance with a suggestion contained in a letter¹¹ on band spectrum notation that was recently circulated.

The values of ω_0 for the two $^2\Pi$ levels are 1030 cm^{-1} for the upper one and 1892 cm^{-1} for the lower level. Consequently one should expect an intensity distribution among the bands that is typical of a molecule whose moments

¹¹ O. W. Richardson, *Trans. Farad. Soc.* **25**, 628 (1928).

of inertia in the upper and lower states differ greatly. Barton, Jenkins and Mulliken¹² have studied the intensity distribution among the β bands that were excited in active nitrogen, and they have found that the principal features of the intensity distribution agree with the predictions of the Condon theory. They have also noted some interesting and definite discrepancies between theory and experiment and the occasion will arise later in the paper for mentioning them.

In the present experiments the most intense β bands correspond to the $v'=0$ progression. Transitions from higher ${}^2\Pi$ levels are either very weak or entirely absent in the discharge. Birge¹³ has pointed out that the $v'=0$ progression in the β bands, as excited by active nitrogen, was very intense relative to the higher progression. In the present experiments they seem to be relatively even more intense than they are in active nitrogen. The similarity between the two methods of excitation as indicated by the above point may be interpreted as showing that the mode of excitation in the present experiments may be exactly the same as that occurring in the afterglow of nitrogen. It is not proposed to discuss here the relationship between the excitation of the β bands and the nature of the afterglow. That will be discussed elsewhere. The present experiments have suggested several questions as to the possible ways in which the β bands can be excited and it is those questions that will be briefly discussed here.

The absence of the β bands from the spectra of ordinary discharges through mixtures of nitrogen and oxygen or through nitric oxide, is of course readily accounted for by the Condon theory and is due to the large change in moment of inertia during the transition $B^2\Pi^0 \rightarrow X^2\Pi^0$. The most probable transition from the $X^2\Pi^0$ level by electron impact would probably result in dissociation of the molecule. Now according to ideas advanced by R. J. Strutt, NO_2 is formed in the air afterglow by the oxidation of NO by ozone. It is possible therefore that highly vibrating nitric oxide molecules are formed by the decomposition of NO_2 in the weak discharge and it is these molecules that are excited by electron impact to yield molecules in the $B^2\Pi^0$ level. It is difficult of course to see just why this level should be favored both by this process and by the one in active nitrogen. It is also difficult to reconcile the above suggestion with the absence or weakness of other than the $v'=0$ progressions.

Before calling attention to two other possible modes of excitation another unique property of the β bands will be mentioned. Barton, Jenkins and Mulliken have called particular attention to the fact that progressions higher than $v'=4$ are absent from the β bands excited in active nitrogen. This is especially striking since in absorption bands up to $v'=5$ have been observed. The above mentioned fact may give the clue to the explanation of the excitation of these bands in both afterglows.

The energy necessary for the excitation of the ${}^2\Pi^0$ level from the normal state of the molecule is 5.65 volts. The energy of recombination of NO is

¹² Barton, Jenkins and Mulliken, *Phys. Rev.* **30**, 175 (1929).

¹³ R. T. Birge, *Molecular Spectra in Gases*, p. 141.

now thought to be about 6.6 volts.¹⁴ Consequently it is possible that the energy of recombination of the nitrogen and oxygen atoms is used to excite the β bands. There are several ways in which this energy transfer can be made and a detailed discussion of these possibilities will be given elsewhere. The interesting point to note here is that when it is necessary to excite a molecular level, in which the separation of the two atoms is much larger than in the initial level, there are ways, in which that can be done, that do not involve a transition from the normal to the excited level. In the present case instead of an increase in separation between the nitrogen and oxygen atoms, as would occur if the excitation were from $X^2\Pi^0 \rightarrow B^2\Pi^0$, there is a decrease in separation arising from the recombination of the two atoms. This may account for both the absence of progressions higher than $v'=4$ in the case of active nitrogen, and for the unusual intensity of the $v'=0$ progression in the present experiments as well as in active nitrogen.

One other method remains and attention has already been called to this in an earlier note by Kinsey¹⁵ and the writer. This method is based on the hypothesis that the excitation of bands by collisions of the second kind does not necessarily obey the Condon theory and that large changes in the separation of two atoms can arise when the excitation is brought about in this way. The presence of metastable molecules in active nitrogen makes the above postulate a plausible one, although the energy of the metastable molecules is such as to make difficult the immediate explanation of the several peculiarities in the bands to which attention has been called. There are hardly enough data on the excitation of bands by collisions of the second kind to warrant any hypotheses, but the possibilities are interesting.

THE INFRA-RED ABSORPTION OF SOME ORGANIC LIQUIDS

BY E. K. PLYLER AND THEODORE BURDINE
UNIVERSITY OF NORTH CAROLINA

(Received February 8, 1930)

ABSTRACT

The infra-red absorption spectra of fourteen organic compounds, including seven alcohols and seven miscellaneous compounds, have been studied in the region from 1μ to 7.5μ . The bands in the region from 1μ to 3μ have been classified as overtones or combination bands of the assumed fundamental bands for the alcohols at about 3.00μ , 3.4μ , 6.8μ , and 9.8μ . By the use of Sappenfield's work for the region from 1μ to 2μ and that of Weniger from 7.5μ to 10μ and the present work a fairly complete idea of the infra-red absorption spectra of the alcohols has been obtained. The intensity relations have been discussed briefly and it was shown that they were in general in accordance with combinations attributed to the different bands. The bands of the miscellaneous organic compounds have been classified, but all the bands have not been included as only the fundamentals at 3.4μ and 6.8μ were used. A probable reason for the similarity of the infra-red spectra of many organic compounds in the region from 1μ to 3μ has been suggested.

INTRODUCTION

AN EXPERIMENTAL study has been made of the infra-red absorption bands of fourteen organic liquids in the region from 1μ to 8μ . The materials used were methyl, ethyl, propyl, butyl, iso-propyl, iso-amyl, and iso-butyl alcohols and m-nitrotoluene, o-nitrotoluene, methyl sulphate, ethyl sulphate, nitromethane, nitrobenzene and ethyl acetoacetate. The purpose of this investigation was to see what similarities existed in the near infra-red absorption bands of some organic liquids of quite different type. Also, it was hoped that several of the more intense bands of each material could be classified as combination bands of the fundamentals.

The infra-red absorption spectra of nearly all the alcohols studied in this work have already been investigated by Weniger¹ in the region from 1μ to 14μ and by Sappenfield² from 1μ to 2μ . The work of Weniger gives one a good representation of the bands to 14μ , but as he used a very thin cell for the entire region many of the smaller bands were not observed. Sappenfield was able, by using cells of different thickness and spectrometer of high resolution, to detect many bands in the region from 1μ to 2μ which had not previously been observed. He classified some of the bands observed by him on the basis of the work of Gapon.³ It was believed that a modification of his classification would be more in accordance with intensity relations. It was thought that it would be of value to extend the experimental observations under high

³ Gapon, Zeit. f. Physik **44**, 600 (1927).

resolution beyond the region of 2μ and to classify the bands found by Sappenheim with those of this region.

EXPERIMENTAL PROCEDURE

The apparatus and the method of measurement were essentially the same as used by the writer in a previous investigation.⁴ It was found necessary to use cells of different thickness in order to observe the weaker bands. These cell thicknesses and the effective slit widths are tabulated in Table 1. The

TABLE I. *The cell thicknesses and the effective slit-width at the thermopile for the different parts of the region studied.*

Region	Thickness of cell	Prism used	Effective slit-width

thickness of the cells in the region from 2.80μ to 3.50μ and from 5.50μ to 7.50μ varied somewhat for each material studied. For example, in the cases of the alcohols it was necessary to have cells about 0.001 mm in order that 20 percent of the incident beam might be transmitted. These thin cells were made by placing a small drop of the liquid on a microscopic cover glass and then placing another cover glass over this. The cell formed in this manner was then pressed very thin and glued around the edges. An approximate value of the thickness was obtained by observing the change in the interference fringes when the cover glasses were pressed together at the center of the cell. The thicker cells were made by separating glass or rock-salt windows with lead foil or sheet lead. All the materials used in this study except two of the alcohols, which were prepared in the chemical laboratory, were obtained from the Eastman Kodak Laboratories.

RESULTS AND DISCUSSION

The experimental results are represented in Figs. 1 to 6 and a list of the observed bands is given in Table II. The region from 2.8μ to 3.6μ was measured with the rock-salt prism in Fig. 3 and with the quartz prism in Fig. 2. Due to the great effective slit width in the region of 3μ for the rock-salt prism, it was not possible to resolve the bands at 3.00μ and 3.40μ . For the alcohols the region from 3.6μ to 5μ has been included in Fig. 3, but it does not contain any intense bands. Also, any bands of much intensity were not observed for the other materials in this region and results obtained were not included in Fig. 6. The relations found to exist between some of the bands of the alcohols are shown in Table III. The combinations given were calculated on the basis that the intense bands observed at 3.00μ , called ν_1^1 , 3.40μ , ν_1 , 6.90μ , ν_2 , and

which were omitted, were due to a combination including a fundamental beyond 12μ which had not been observed rather than to a combination of the known fundamentals. Fundamental bands have been observed for several

organic compounds in this region and it is probable that they exist for these materials, and if they were known, probably a more complete classification could be made.

By a study of the experimental results it is seen that there is considerable overlapping of the bands in the near infra-red region. Unless high resolution is used the less intense maxima are not observed. Also often a weak band occurs near an intense one and changes the shape of the more intense absorption curve, but does not cause the absorption curve to change sufficiently for it to be detected. This effect is especially noticeable in the alcohols in the region from 1.4μ to 1.6μ .

Sappenfield² has used the suggestion of Ellis⁵ that the organic liquids may be arranged as a series of overtones of the 3.4μ band and thus four of the bands are classified. This classification appears probable and the writer has included it in the present arrangement. The band at 0.92μ was classified as $4\nu_1$ and the band at 1.20μ as $3\nu_1$, and $2\nu_1$ and ν_1 were calculated from these bands. However, as a small error in $4\nu_1$ and $3\nu_1$ would cause a large error in ν_1 it was thought that the observed value of ν_1 was more accurate and it was used in the calculation of the combination bands. In like manner ν_1^1 was checked by using the bands at 1.02μ as $3\nu_1^1$ and 1.53μ as $2\nu_1^1$, but in combination bands the observed value of ν_1^1 was used. It should be noted in some cases there is a considerable difference between the calculated and observed bands in the case of $2\nu_1$ at about 1.75μ . This difference is probably brought about by the fact that the combination $\nu_1^1 + \nu_2 + \nu_3$ also gives rise to a band at near the same wave-length. In the case of tertiary butyl alcohol and secondary butyl alcohol both maxima were found.

By an examination of the results obtained in this work and those obtained by Weniger¹ the intensities of the assumed fundamentals are in the order ν_3, ν_1^1, ν_2 , and ν_1 . Of the combination bands obtained by adding two fundamental bands $\nu_1^1 + \nu_3$ should probably be the most intense and $\nu_1 + \nu_2$ the least intense. However, these two bands fall in the same region of the spectrum and were not separated. The intensity of $\nu_1^1 + \nu_1$ in the region of 1.60μ is somewhat less than the intensity of $\nu_1^1 + \nu_2$ at 2.09μ and the intensity of $\nu_1^1 + \nu_1 + \nu_3$ is less than that of $\nu_1^1 + \nu_1$. The decrease in intensity of the successive overtones of ν_1^1 and ν_1 is large. Due to the considerable overlapping in the bands, it is not possible to make a careful comparison of the intensities of the different combinations, but in the bands where the intensities could be checked the combinations given in Table III were upheld.

In Table IV the assumed fundamentals ν_1 at 3.40μ and ν_2 at 6.80μ and combination bands of M nitrotoluene, methyl sulphate, nitromethane are given. Only slight differences occur for the other materials studied and they have not been included. Since only two fundamentals are known, several of the bands in the near infra-red could not be attributed to simple combinations. They have been omitted for they are possibly due to combinations of ν_1 and ν_2 with bands in the region of 10μ to 12μ and 15μ to 18μ . In these

⁵ Ellis, Phys. Rev. 31, 916 (1928).

regions bands have been shown to exist for several of methyl and ethyl compounds by different observers.⁶

While it must be recognized that the infra-red absorption spectra of each substance are different even though they may be only slightly different chemically, yet the great similarity in the absorption spectra of quite different organic compounds in the region from 1μ to 3μ is readily observed. This similarity in the near infra-red region is probably due to the fact that many

organic compounds have fundamentals at about 3.3μ and 6.8μ , and in several cases also, fundamental bands are in the region from 8μ to 12μ and from 12μ to 18μ . By the combinations of these bands the near infra-red spectra are somewhat similar in appearance, but in the region from 8μ to longer wavelengths a considerable difference is found in the spectra of similar organic compounds. An examination of the results of Coblentz⁶ shows this for a large number of organic compounds.

MEASUREMENT OF THE DIELECTRIC CONSTANT AND INDEX OF REFRACTION OF WATER AND AQUEOUS SOLUTIONS OF KCl AT HIGH FREQUENCIES

BY F. H. DRAKE, G. W. PIERCE AND M. T. DOW
CRUFT LABORATORY, HARVARD UNIVERSITY

(Received February 10, 1930)

ABSTRACT

Dielectric constant of distilled water.—The dielectric constant of distilled water was measured with a vacuum tube source of voltage throughout a range of periods extending from about $T=1.31 \times 10^{-8}$ second to $T=8.49 \times 10^{-8}$ second corresponding to vacuum wave-lengths of 3.918 meters to 25.47 meters. The value obtained for the dielectric constant is $\epsilon=78.57$ at 25°C and is independent of the period within the above range of periods.

Temperature coefficient of dielectric constant for distilled water.—The values of the dielectric constant ϵ obtained for various temperatures t between 10°C and 60°C satisfy the empirical equation

$$\epsilon_t = 78.57[1 - 0.00461(t - 25) + 0.0000155(t - 25)^2 \dots].$$

Between 4°C and 10°C the applicability of this equation is somewhat uncertain.

Dielectric constant of conducting solutions.—With distilled water, tap water, and aqueous KCl solutions of conductivity ranging from 0.97×10^7 e.s.u. to 178×10^7 e.s.u., and separating the conduction effects from the dielectric effects, we found the dielectric constant only slightly dependent on the ionic concentration of the solution and nearly the same as that of pure water. The errors of measurement are of the order of 0.1 percent for low conductivities but, because of attenuation, become of the order of 1 percent at the high concentrations of the salt.

Method.—The method employed consists in the measurement of standing electric waves between a pipe and a wire concentrically located within the pipe. The liquid is the dielectric between the wire and the pipe. The frequencies employed were accurately measured by a piezo crystal standardizing a zero beat method, and the half wave-length within the dielectric were obtained by moving a piston in the liquid and observing reactions on the source.

A theoretical discussion of the method is given.

INTRODUCTION

SOON after the discovery of piezoelectric oscillators and their adaptation to the production of constant frequencies of oscillations¹ we began an investigation of waves on wires. The frequencies of an electric oscillator were determined by comparison with the piezoelectric standard and the lengths of the resulting standing waves on two parallel wires were measured. In this way

¹ G. W. Pierce, "Piezoelectric Crystal Resonators and Crystal Oscillators Applied to the Precision Calibration of Wavemeters," *Proc. Am. Acad. of Arts and Sciences* 59, No. 4 (1923). "Piezoelectric Crystal Oscillators Applied to the Precision Measurement of the Velocity of Sound etc." *Ibid.* 60, No. 5 (1925).

an absolute determination of the ratio of the electro-magnetic to the electro-static unit of electric quantity was attempted. After about a year of work on this problem it became apparent that the influence of surrounding objects led to errors and uncertainties which could not be sufficiently reduced with the parallel wire system.

To avoid this stray-field trouble it occurred to us to confine the field to the space between a central wire and a surrounding tube. This apparatus we have now had in operation for several years. The investigation with air or vacuum as the dielectric is not yet good enough for publication since on account of certain small mechanical inequalities of the pipe-system the precision desired has not been attained. We have, however, obtained accuracies better than one-tenth of one percent, and as a by-product to the primary research on the ratio of the units we have employed a similar apparatus in the present investigation.

DETAILS OF THE CONCENTRIC PIPE SYSTEM

The present method of determining the index of refraction of poorly conducting liquids resembles the older well-known scheme of measuring the index by comparing the length of the standing waves on Lecher wires immersed in the liquid with the length of the corresponding air waves. The method is, however, here refined by replacing the wires of the Lecher system by a brass pipe having a copper wire centrally within it along the axis of the pipe, with the solution in the pipe. The pipe and wire are excited by a vacuum tube oscillator at frequencies accurately known by their harmonic relationship with a piezoelectric quartz standard. A movable brass plunger making spring contacts with the pipe and wire and carrying a calibrated rod of the same material above it permits accurate settings at the positions of maximum reaction, which are half a wave-length apart. A sensitive galvanometer, recording changes in the plate current of the oscillator exciting the pipe and wire, indicates the half wave positions as the plunger moves along the pipe. From the known frequencies and the wave-length in the dielectric the velocity of the electric waves in the dielectric is computed.

As a device for producing standing electric waves the system of pipe, wire, and plunger has the outstanding advantage of confining the electric field to the medium between the pipe and wire. Suppose, for example, a set of parallel wires is immersed in a water tank. If the tank is small, an appreciable part of the electric field associated with the charges on the wires may be quite outside the water; difficulties also arise from reflections at the boundaries of the water; and an increase in size of the tank only reduces and does not eliminate these disturbances. For the longer waves in the present experiments the tank would need to be enormous. In the case of the pipe and wire system, on the other hand, the electric currents are confined to the inner surface of the pipe and the outer surface of the wire, so that the electric field has radial symmetry and is completely within the dielectric.

Fig. 1 shows in detail the experimental arrangements adopted. The brass pipe, 3.7 meters long and having an inside diameter of 4.1 cm and a wall-

thickness of 0.32 cm, was mounted vertically against a wall between two neighboring floors of the Cruft laboratory. A hard-drawn copper wire 0.163 cm in diameter was centrally fixed in the pipe held at the lower end by a canvas bakelite cap, and at the upper end by a bakelite strip. In order to make a watertight joint at the lower end, the bakelite cap was screwed to the end of the pipe hard against a thin cardboard gasket which had been boiled in paraffin. The pipe was filled from the top and emptied through a small hole (normally closed with a bakelite plug) in the bakelite cap.

Fig. 1. Arrangement of apparatus.

Two electric oscillators were used to cover the range from 4 to 25 meters vacuum wave-length: one, an oscillator designed particularly for high frequencies, covered the range from 4 to 5 meters; the other, an ordinary Hartley circuit oscillator with parallel plate supply, was used from 5 to 25 meters. These two oscillators and the piezo-electric oscillator, employing a quartz crystal mounted in vacuum, were placed in a sheet iron box at the lower end of the pipe. The pipe protruded below the cover of this box about 10 cm, and made good contact with the cover by means of a bronze flange clamped about the pipe and bolted to the cover. Shielded cables included all electrical connections from the observing position at the top of the pipe to the various oscillators in the box below. The electric oscillator was coupled to the lower end

of the pipe-wire by a single lead through a small condenser, which was variable in order to permit equal coupling at all frequencies. The adjustment to zero beat between the electric oscillator and a harmonic of the crystal oscillator was accomplished by varying a condenser of the electric oscillator for course adjustment; and finally, for fine adjustment, a resistance in the plate circuit of the electric oscillator was varied.

The reflection of waves at the input end occurs principally at the lower surface of the water column, that is, the upper surface of the bakelite cap, due to the large discontinuity in dielectric constants here. The waves are reflected at the other end by a solid brass plunger making spring contact at its lower face with the pipe and wire, and moved by a brass rod 0.6 cm in diameter firmly fixed to the plunger, and upon which are cut marks 50 cm apart. As the piston is moved the current in the plate circuit of the driving oscillator remains constant until the piston is in the neighborhood of a potential node, and then shows a marked change in value as the node is passed due to the reaction of the waves on the oscillator. These nodal positions can be determined with an accuracy of about 0.1 mm with water as dielectric.

STANDARD OF FREQUENCY

The length of a wave in vacuum was computed from the velocity of light and the frequency of the particular harmonic employed. The piezoelectric crystal used as a standard vibrates at a temperature of 25°C with a frequency $f_0 = 5.886 \times 10^6$ cycles per second. In Table I are given the periods and half

TABLE I. *Periods and vacuum half wave-lengths for different harmonics of the crystal standard.*

wave-lengths in vacuum corresponding to the employed harmonics of this crystal from the second to the thirteenth inclusive. Harmonic numbers are tabulated in the first column under p . The fundamental frequency is characterized by $p = 1$. The periods (T) are in seconds, and the vacuum half wave-lengths ($\lambda_0/2$) are in centimeters.

THEORY

The velocity of propagation of electric waves along coaxial tubes in the ratio of the angular velocity of the exciting current to the retardation angle per unit length of the tubes. That is, if β is retardation angle per unit length of tube, $\omega/2\pi$ the frequency of electric oscillator and v the velocity of electric waves of frequency, $\omega/2\pi$, then

$$v = \omega/\beta. \quad (1)$$

The retardation angle β depends rather simply upon two coefficients of the line: one involving the series resistance and inductance per loop unit length

of the line, and the other involving the capacity and leakage conductance per loop unit.

Let r , l , c , g be respectively resistance, inductance, capacity, and leakage conductance per loop unit of length for the pipe and wire; μ , ϵ be respectively the permeability and dielectric constant of the medium between the pipe and the wire.

$$\begin{aligned}\eta &= r/l\omega \\ s &= g/c\omega \\ f(h) &= + \left(\frac{(1+h^2)^{1/2} + 1}{2} \right)^{1/2} \\ g(h) &= + \left(\frac{(1+h^2)^{1/2} - 1}{2} \right)^{1/2}.\end{aligned}\quad \text{See Footnote 2.}$$

It will be later shown that in these experiments $\eta S < 1$ so that, since $\mu = 1$, the retardation angle β is given by the leaky-line equation:

$$\beta = \frac{\omega}{c'} \epsilon^{1/2} (1 - \eta s)^{1/2} f(h) \quad (2)$$

where

$$h = \frac{\eta + s}{1 - \eta s}$$

c' = ratio of the units.

Since from Maxwell's theory the velocity of electromagnetic waves in vacuum is numerically equal to the ratio of the units (a fact that we have checked experimentally to better than one part in 3000), the index of refraction, corresponding to Eq. (2), is, in view of (1),

$$N = \epsilon^{1/2} (1 - \eta s)^{1/2} f(h). \quad (3)$$

The index N is directly measured in these experiments as the ratio of the wave-length in vacuum to the wave-length in the water.

Eq. (3) then gives a means of calculating the dielectric constant ϵ from values of N and the line coefficients η and s . It will be noted that s and h both involve ϵ through c , the capacity per loop unit of length.

With the object of still further simplifying (3) let us examine the magnitudes of η and s for the actual line. By substitution of the values of g and c in terms of the inner radius of the pipe and the outer radius of the wire it may be shown that

$$s = \frac{2\gamma T}{\epsilon}$$

² Cf. G. W. Pierce, "A Table and Method of Computation etc," Proc. Am. Acad. 57, No. 7 (1922), where these functions, which occur frequently in electromagnetic theory, have been computed and tabulated for values of h between 0 and 250.

where γ is the specific conductivity of the medium between pipe and wire in e.s.u. and T is the period in seconds corresponding to angular velocity ω . Since it is known before hand that ϵ is sensibly independent of frequency, s will be a maximum where the product $T\gamma$ is largest. This occurred in our experiments for waves of period 2×10^{-8} second and for a conductivity of 178×10^7 e.s.u. Since ϵ is approximately 78.5 for water we find

$$s \leq 0.96.$$

The exact value of η for a particular frequency cannot be calculated unless the value of the resistance per loop unit of pipe and wire is known. A value of η sufficiently near the actual value to discuss negligibilities in Eq. (3) may, however, be obtained by assuming that the resistance of the pipe is negligible in comparison with the resistance of the wire.

With this approximation it may be shown, by putting in numerical values, that for the conditions in the present investigation

$$\eta \leq 0.0035$$

and

$$\eta s \leq 0.0034.$$

These results permit considerable simplification in Eq. (3). In the first place, it is evident from inspection of tabulated values of the function $f(h)$ that for all values of h for which $f(h)$ contributes to Eq. (3) a multiplier different from unity the expression for h may be reduced to

$$h = s = 2\gamma T/\epsilon$$

without affecting the accuracy by one part in a thousand. Finally, the maximum error which would be produced by neglecting ηs in comparison with unity under the radical of Eq. (3) will be approximately $\eta s/2$ or about one part in six hundred. But so large an error would occur only for the highest conductivities and lowest frequencies, for which, because of high damping, the accuracy of the experimental determinations is reduced to approximately one part in two hundred; so that the final accuracy of computed observations will not be appreciably affected if we write for all cases in these experiments,

$$N = \epsilon^{1/2} f(h) \quad (4)$$

where

$$h = 2\gamma T/\epsilon$$

Eq. (4) is the theoretical expression for the index of refraction of water and aqueous solutions for the particular frequencies, conductivities, and physical dimensions employed in the work herein described. γ and ϵ are respectively the conductivity in e.s.u. and dielectric constant in e.s.u. of the water or the solution, and T is the period of the electric waves.

MEASUREMENTS OF THE DIELECTRIC CONSTANT OF DISTILLED WATER IN THE RANGE OF PERIODS 1.31×10^{-8} TO 8.49×10^{-8} SECOND

Table II gives a series of results obtained for distilled water at approximately 25°C. The first column contains the number of the harmonic of the

standard crystal oscillator with which the electric oscillator was held at zero beat-frequency. From Table I the corresponding values of the half vacuum wave-length $\lambda_0/2$ are taken and are tabulated in column II. Column III contains the temperature, column IV the measured value of half wave-length in the water at temperature t , conductivity γ ; column V the half wave-length reduced to 25°C by use of the coefficient obtained below; column VI the value of index of refraction N at 25°C. The next to the last column contains approximate values of $2\gamma T/\epsilon$, in which only a rough value of ϵ is needed. For $h=0.0212$, in the top line of the table, the value of $f(h)$ as defined above is 1.00005 and can be replaced by unity. For larger values of $p2\gamma T/\epsilon$ is still nearer unity; so throughout the table the correction for γ is negligible, making ϵ in the last column of this table the same as the square of the sixth column.

13	195.9	"	22.11	22.09	8.870	—	78.68
Mean = 78.57							Mean departure = ± 0.05

The mean value of ϵ at 25°C is

$$\epsilon_{25} = 78.57 \pm 0.05$$

for distilled water.

MEASUREMENTS OF THE TEMPERATURE COEFFICIENT OF THE DIELECTRIC CONSTANT OF DISTILLED WATER

Water temperatures from 3° to 60°C were obtained by filling the pipe with water just above the freezing point, allowing the pipe to warm slowly to room temperature, taking velocity measurements as different temperatures were reached. For higher temperatures heat was applied to the pipe by passing current through several coils of resistance wire wound around it, as shown in Fig. 1. The pipe was covered with asbestos packing to prevent rapid temperature changes. This precaution, in addition to the stirring produced by moving the plunger, insured a practically uniform temperature throughout the water in the pipe except near the ends, which regions could not be included in the temperature coefficient measurements. The temperature of the water before and after the wave-length measurement was read by a mercury thermometer provided with a cylinder for collecting water and holding it

around the thermometer bulb as the thermometer was raised to read. This method allowed temperatures to be determined within about 0.2°C once the operator developed sufficient speed in pulling up the thermometer and taking readings.

The values obtained for ϵ_t were found to satisfy the empirical equation

$$\epsilon_t = 78.57[1 - 0.00461(t - 25) + 0.0000155(t - 25)^2 \dots]$$

for temperatures between 10° and 60°C , as seen by reference to Fig. 2 where the curve is the curve of the equation and the points are observed values of ϵ_t . Three different vacuum wave-lengths λ_0 were employed, and the points for the three different values of λ_0 all fall near the curve in the specified range of temperatures 10° to 60°C .

Fig. 2. Locus of empirical equation for the dielectric constant of distilled water as a function of temperature. Observed values for three wave-lengths are included.

For temperatures between 5° and 10°C there is a significant departure from the curve of the equation and the longer wave-lengths seem to give values of ϵ_t departing farther from the curve. These anomalies appear at values of temperature for which the water has anomalous behavior as to density.

INDEX OF REFRACTION AND DIELECTRIC CONSTANT OF TAP WATER AND OF AQUEOUS KCL SOLUTIONS

Tables III, IV, and V give measured values $\lambda/2(t, \gamma)$ of the half wave-length in tap water of conductivity $\gamma = 11.9 \times 10^7$ e.s.u., aqueous KCl-solu-

tion of $\gamma = 47 \times 10^7$ e.s.u. and KCl-solution of $\gamma = 178 \times 10^7$ e.s.u., all measured for the various values of $\lambda_0/2$ indicated in the second column of each table. Using the temperature coefficient formula of the preceding section and ex-

tracting the square root we have the approximate relation $\Delta\lambda/\lambda = -0.0023\Delta$ for change of wave-length with change of temperature, and have reduced the measured values of $\lambda/2$ to the values at 25°C recorded in the column marked

" $\lambda/2(25, \gamma)$." Dividing this into $\lambda_0/2$ we obtained $N(25, \gamma)$. Then employing the formula $N = \epsilon^{1/2}f(h)$, which has above been shown to be a correct approximation within the limits of period and conductivity here occurring, we have calculated the values of ϵ given in the last columns of the tables. In examining these results it should be borne in mind that large conductivities and long waves have a higher attenuation and introduce greater difficulties of measurement, which accounts for the fact that departures of readings from their average values are greater with the larger conductivities and with the longer vacuum wave-lengths. (In fact with the solution of Table V the two nodal points necessary for determining the $\lambda/2$ in the solution could not be obtained for $\lambda_0/2$ greater than 318.4 cm). Taking into account these larger sources of error we see that the addition of salts in sufficient quantity to increase the conductivity from 0.97×10^7 to 178×10^7 increases the index of refraction, in

Fig. 3. Theoretical variation of the index of refraction of tap water ($\gamma = 11.9 \times 10^7$) and aqueous solutions of KCl ($\gamma = 47 \times 10^7$ and $\gamma = 178 \times 10^7$) with wave-length, assuming the true dielectric constant ϵ independent of the conductivity. Observed points are included.

a manner dependent on γ and λ_0 , but when the effects of conductivity are eliminated so as to give the true dielectric constant ϵ , the value obtained for ϵ differs from ϵ of distilled water by less than 1 percent. It is not yet known whether this small difference is due to errors introduced by the high attenuation at the higher conductivities; errors which do not arise when water or low-conductivity solutions are employed.

Fig. 3 exhibits graphically as a function of wave-length the values of the index of refraction N taken from the sixth column of Tables III, IV, and V. The smooth curves are the loci of Eq. (4) for the conductivities listed above the tables; and are plotted assuming that ϵ is independent of γ and of the same value as for distilled water. The fact that the observed values lie near these theoretical curves is evidence for the validity of the assumption that ϵ is sensibly independent of γ for the conductivities here employed.

MEASUREMENTS OF THE DIELECTRIC CONSTANTS
OF CONDUCTING MEDIABY JEFFRIES WYMAN, JR.
CRUFT LABORATORY, HARVARD UNIVERSITY

(Received February 10, 1930)

ABSTRACT

It is possible to build small, rigid circuits which have natural periods determined by the medium in which they are immersed. If $T\gamma$, the product of the natural period of the circuit and the conductivity of the medium, is sufficiently small, this period is proportional to the square root of the dielectric constant of the latter. On the basis of this fact measurements have been made of the dielectric constant of water from 0° to 100°C to an accuracy of 0.2 percent or better and covering a range of frequency from $T = 1.4 \cdot 10^{-8}$ to $81 \cdot 10^{-8}$. If $T\gamma$ is not sufficiently small, the period is affected by the conductivity of the medium in a complicated way and cannot be used to obtain the dielectric constant. With the smallest circuits used measurements of the dielectric constants of liquids having conductivities as high as 100 times that of water can be made.

A FEW months ago I became interested in the question of the measurement of the dielectric constants of solutions of certain biological substances, chiefly various proteins which can be prepared in very pure form. Such measurements have an interest in view of existing speculations.¹

The materials in question are for the most part best available in aqueous solution, where they behave like ampholytes containing very weak acid and basic groups.² Under the most favourable conditions concentrated solutions (20–30%) can be obtained having conductivities as low as ten times that of distilled water. They are, moreover, laborious to prepare in more than small quantities. Any method suitable for the study must therefore (1) be appropriate for use with material having a conductivity approaching that of a dilute salt solution and (2) be applicable to small amounts of the substance to be investigated.

The method described in this paper seems to be the simplest and most accurate one which meets these requirements and ought to be generally useful. It has, moreover, some interest in connection with the behaviour of circuits at high frequencies. The following other methods may be mentioned briefly.

The well-known bridge method of balancing the resistance and capacity of a cell containing the unknown liquid for an alternating e.m.f. of fixed frequency has been developed in great detail by Nernst.³ It requires only

¹ Debye, *Polar Molecules*, Chemical Catalogue Co., New York, 1929.

² E. J. Cohn, *Physiological Reviews* 5, 350 (1925).

³ See Nernst, *Zeits. f. Phys. Chemie* 14, 622 (1894). The method has been used by B. B. Turner, *Zeits. f. Phys. Chemie* 35, 428 (1900), to measure the dielectric constant of water and several other liquids. It has also been used by Ratz, *Zeits. f. Phys. Chemie* 19, 94 (1896) and

small amounts of material but it is not suitable for frequencies above about 10^8 sec^{-1} , such as are necessary for measurements on liquids having conductivities much greater than that of distilled water.

Another well-known method makes use of standing waves produced by resonance in parallel wires. The wave-length on the wires is inversely proportional to the square root of the dielectric constant of the surrounding medium provided conductivity effects may be neglected. This method may be used at very high frequencies (greater than $3 \times 10^8 \text{ sec}^{-1}$) in connection with spark oscillators, but it requires considerable amounts of material and its accuracy is not very great.⁴

A modification of this method, developed by Drude, requires much less material; but the accuracy is no greater than that of the original method and there is the disadvantage that the apparatus must be calibrated with known liquids.⁵

One of the earliest of the electrostatic methods is based on a comparison of the attraction between the plates of a condenser charged to a given difference of potential and separated first by air and then by the unknown liquid. The magnitude of the attraction is proportional to the dielectric constant of the medium between the plates. The method has been used successfully with direct and alternating sources of e.m.f. The only apparent objection to it is that it is inconvenient for small amounts of material.⁶

A modification of this method makes use of the torque acting on a small conducting body (Fürth gives this body the form of an ellipsoid of revolution) suspended in the field between the plates of a condenser. The magnitude of this torque is a function of the dielectric constant of the medium separating the plates.⁷

Harrington, *Phys. Rev.* **8**, 581 (1916) on water. More recently it has been used by C. P. Smyth, *Journ. Amer. Chem. Soc.* **49**, 1030 (1927), **50**, 1536 (1928), in the study of organic liquids and liquid mixtures; also by Sack, *Phys. Zeits.* **28**, 199 (1927) in the study of salt solutions.

⁴ This method is based on the work of Lecher and of Blondlot on waves in wires. It was first used by Cohn u. Heerwagen, *Wied. Ann.* **43**, 343 (1891), and later more extensively by Drude, *Wied. Ann.* **55**, 633 (1895); **58**, 1 (1896); **59**, 17 (1896). See also *Zeits. f. Phys. Chemie* **23**, 270 (1897). It has also been used by Marx, *Wied. Ann.* **66**, 603 (1898), Colley, *Phys. Zeits.* **10**, 471 (1909); **10**, 657 (1909); **11**, 324 (1910), Rudop, *Ann. d. Physik* **42**, 489 (1913), Weichman, *Phys. Zeits.* **22**, 535 (1921), and Mie, *Phys. Zeits.* **27**, 792 (1926), for the most part on water. It has been applied by Deubner, *Ann. d. Physik* **84**, 429 (1927) to the study of dilute aqueous salt solutions.

⁵ This method is described by Drude in *Zeits. f. Phys. Chemie* **23**, 270 (1897). The value of the dielectric constants for a large number of substances obtained by the two methods are given. The method has been employed recently by R. Fürth, *Ann. d. Physik* **70**, 63 (1923) for the study of several organic and biological substances, and still more recently by Voigt, *Zeits. f. Physik* **44**, 70 (1927) for obtaining measurements on dilute salt solutions.

⁶ Much of the early work on water and other liquids was carried out by this method: Cohn and Aarons, *Wied. Ann.* **33**, 14 (1888); Tereschin, *Wied. Ann.* **36**, 792 (1888); Heerwagen, *Wied. Ann.* **49**, 272 (1893); Franke, *Wied. Ann.* **50**, 163 (1893). More recently Carman, *Phys. Rev.* **24**, 396 (1924) has revived the method and used it on water at a frequency of 60 cycles. Schmidt, *Phys. Rev.* **30**, 925 (1927), following the procedure of Carman, has applied it to dilute salt solutions.

⁷ The method was used at the suggestion of Nernst by Smale, *Wied. Ann.* **57**, 215 (1897)

A reflection method using polarized waves of very short wave-length (about 3 cm) has been used by Cole⁸ and Merczing⁹ to study the absorption bands of water. It is very inexact and of doubtful validity.

There is a very accurate method based on the principle of standing waves in wires described by Drake Pierce and Dow in a preceding paper of this journal. This method however requires very large amounts of material and is for this reason unsuited to the present requirements.

There is lastly another form of resonance method, which is of more interest in the present connection. A circuit, which we will call the *resonator*, containing the unknown, is brought to resonance with an *oscillator*, maintained at a fixed frequency, by adjustment of a variable condenser. This condenser is calibrated and placed in parallel with the cell or fixed condenser for the unknown, and from its settings when the cell is filled first with air and then with the unknown, the dielectric constant of the latter is calculated. Unfortunately this method is unsatisfactory at high frequencies, owing to stray capacity effects in the resonator. These increase with the frequency and may be expected to change with adjustments of the variable condenser. They can never be determined directly and can only be allowed for by calibration of the whole resonator in terms of known liquids introduced into the cell. This procedure, however, has the following disadvantages: (1) it limits the accuracy and range of all new determinations to that of previous measurements of the standard liquids; (2) it is impossible to get good standards of high dielectric constants (greater than about 30) since water itself is not known to great accuracy; (3) it is constantly necessary to check up on the calibration of the circuit.¹⁰

In order to avoid these difficulties and at the same time profit by the accuracy with which it is possible to make settings by a resonance method it was suggested to me by Professor G. W. Pierce that it might be possible to make a small, rigid resonator which could be entirely immersed in the liquid to be studied, so that all capacities of the circuit would be included alike in the medium. The plan then demands an inversion of the usual procedure of tuning the resonator to the oscillator; instead of this, the frequency of the oscillator is to be varied until it corresponds with the natural period of the resonator, first in air, then in the liquid. These frequencies can then be used to obtain the dielectric constant.

on water. It has been discussed at length by Fürth, *Zeits. f. Physik* 22, 98 (1924). Peckhold, *Ann. d. Physik* 83, 427 (1927), has employed it in the study of salt solutions.

⁸ Cole, *Wied. Ann.* 57, 290 (1896).

⁹ Merczing, *Ann. d. Physik* 33, 1 (1910); 34, 1015 (1911).

¹⁰ Resonance methods of this type have been used by the following observers: Thwing, *Zeits. f. Phys. Chemie* 14, 286 (1894); Niven, *Proc. Roy. Soc.* 85A, 139 (1911); Hyslop, and Carman, *Phys. Rev.* 15, 243 (1920); Preuner and Pungs, *Phys. Zeits.* 20, 543 (1919); Jackson, *Phil. Mag.* 43, 492 (1922); Lattey, *Phil. Mag.* 41, 829 (1921); Kerr, *Journ. Chem. Soc.* 128, 2796 (1926); Williams, *Journ. Am. Chem. Soc.* 48, 1888 (1926) and later; Fritts, *Phys. Rev.* 23, 345 (1924); Walden, Ulrich, and Werner, *Zeits. f. Phys. Chemie* 115, 177 (1925); Kjansky, *Zeits. f. Physik* 52, 743 (1928); Hellmann and Zahn, *Ann. d. Physik* 86, 687 (1928) and Kniekamp, *Zeits. f. Physik* 51, 95 (1928) discuss the method.

After a certain amount of experimentation it was found possible to build compact all metal resonators having natural periods of the desired magnitude. The period of a resonator diminishes with its size, and for a given resonator the period is of course greater in liquids of high dielectric constant. Resonators having a frequency of about 10^8 sec^{-1} in water are small enough to be satisfactorily immersed in 15–20 cc of liquid. This amount of liquid is found to include enough lines of force so that the results are unaffected by parts of the field not included.

The question now arises as to the relation between the natural period of a resonator and the dielectric constant of the medium surrounding it. It is of course well known that if we can treat a circuit as composed of lumped capacity C , inductance L , and resistance R , arranged in series, it will have an impedance given by

$$(R^2 + (L\omega - 1/C\omega)^2)^{1/2}.$$

This will be a minimum at a frequency, called the resonant frequency, given by

$$\omega = 1/(LC)^{1/2}$$

corresponding to the natural period of the circuit.¹¹ If C_0 is the capacity of the circuit in air, and C_1 its capacity in a medium of dielectric constant ϵ , then

$$C_1 = \epsilon C_0.$$

If ω_0 and ω_1 give the corresponding natural periods, then, since L is constant,

$$\epsilon = \omega_0^2 / \omega_1^2. \quad (1)$$

If we could regard our resonators as circuits of lumped capacity, inductance, and resistance, this would make the determination of the dielectric constant

* Calculated from temperature data given below.

by the proposed plan very simple. Now there is evidence, to be given below, that we cannot make such an assumption about the resonators; nevertheless

¹¹ We use ω for convenience. It is to be noted that ω , the natural period T , the resonant frequency f , and the corresponding wave-length λ in free space are given by the relations $\omega/2\pi = f = 1/T = 3 \cdot 10^8/\lambda$.

it appears that, if we can neglect the conductivity of the medium, we can still use Eq. (1) to compute the dielectric constant. The justification of this lies in the fact that the results obtained on water with the use of this assumption are consistent among themselves and agree with other observations. The measurements on water were made at various frequencies with a variety

Fig. 1. Types of resonators. a, cylinder type: natural period in air, $8 \cdot 10^{-8}$ sec.; size 13×20 cm. b, cylinder type: natural period, 10^{-8} sec.; size 5×7 cm. c, cylinder type: natural period, $2 \cdot 10^{-9}$ sec.; size $8 \cdot 6$ cm. d, spiral type: natural period, 10^{-9} sec.; diameter, 1.7 cm.

of resonators. Some of these had the form of concentric cylinders and others of spirals. (See Fig. 1.) The results obtained are given in Table I. The values of E were calculated from the observed frequencies by Eq. (1). With one exception they are all in agreement within the experimental error of the determination of the frequencies, and they also agree with values obtained by other methods. The one exception is in the case of the result obtained with

the largest resonator of all at a relatively low frequency. There is no doubt that the discrepancy in this case is due to the effect of conductivity which increases with decreasing frequency and may be expected on theoretical grounds to become evident at about this frequency for water. This close agreement in the values of ϵ is certainly a justification of the application of Eq. (1) to calculate the dielectric constant from the frequency in cases where conductivity of the dielectric may be neglected.

It should be observed in connection with this procedure that it is not possible in all cases to determine $\omega_0 = 2\pi f_0$ directly. If f_1 , the frequency of the resonator in water, is greater than about 1.4×10^7 , $f_0 = \epsilon^{1/2} f_1$ is greater than about 12×10^7 and lies above the upper range of the oscillator—about 12×10^7 . In such cases, however, it is easy to obtain f_0 by determining f_l , the frequency of the resonator in any intermediate liquid l , whose dielectric constant is immediately measured by a larger resonator for which f_0 is known directly. This liquid may be chosen as having low conductivity, and so introduces no trouble on that ground. It need have no especial purity or composition, since its dielectric constant is determined for the occasion. This practice was made use of in determining the values of f_0 for the smaller resonators and is involved in the above determinations of ϵ for water at the higher frequencies. The auxiliary liquid employed was acetone or a mixture of acetone and gasoline. Of course it is evident that each additional measurement of a frequency introduces errors which are accumulated in the final result and such extra steps are to be avoided if possible.

There is no need to describe the vacuum tube oscillator in detail. It was built about a 299X Cunningham tube with the base removed for operation at higher frequencies. The oscillation was set up between the plate and the grid; its frequency was controlled by interchangeable inductances and a rotating condenser driven by a reducing gear and equipped with a dial bearing a vernier. At the lowest frequencies a Hartley circuit was sometimes employed.

The frequency of the oscillator was determined in terms of the frequency of a quartz crystal according to a method described by Pierce.¹² The oscillator was permanently coupled, inductively, with the crystal circuit so as to give audible beats whenever set to the frequency of one of the harmonics of the crystal. These harmonics serve as standard frequencies and are identified by means of a wave meter. From the dial readings of the oscillator corresponding to several nearby harmonics of the crystal, the frequency corresponding to any intermediate setting of the oscillator may be determined by graphical interpolation. The frequency of every setting of the oscillator during the course of a measurement was always obtained directly in this way.

In the above measurements the criterion for resonance was maximum reaction of the resonator on the oscillator. The resonator, suspended by a fine thread in the medium in question, is placed in the field of the oscillator at a distance of 15 to 50 cm from its coil. The frequency of the oscillator is then varied until there is a sudden drop, or rise, in the plate current. This

¹² Pierce, Proc. Amer. Acad. Arts and Sciences 59, No. 4 (1923).

effect on the plate current of the oscillator undoubtedly accompanies a sharp change in the oscillatory current itself and is taken as the indication of maximum reaction. The corresponding frequency of the oscillator is then determined, according to the method just described, without altering the positions of resonator or oscillator. That in the case of water, or any medium whose conductivity may be neglected under the conditions of measurement, the frequency giving maximum reaction back on the oscillator is the same which gives maximum current in the resonator, corresponding to Eq. (1), was determined by means of a resonator containing a hot wire element (described below). It was found in a test case with water that maximum current was induced in the resonator at a wave-length $\lambda = 5.125$ M; whereas maximum reaction on the oscillator occurred at $\lambda = 5.124$ M. This result accords with the applicability of Eq. (1) to settings obtained by the reaction method.

Fig. 2. The dielectric constant of water (ϵ) as a function of temperature.

The sharpness of any resonance setting is of course greater the lower the conductivity of the medium in question. In the case of distilled water the accuracy of a resonance setting at a frequency greater than about 4×10^6 is nearly equal to the accuracy of the determination of the frequency—that is, good to about 0.02 percent. The accuracy of the determination of the resonance frequency itself is thus about 0.04 percent. Any determination of the dielectric constant of water involves the determination of not less than two resonance frequencies, one in air and one in water. The best individual values of the dielectric constant of water obtained by this method are therefore accurate to about 0.1 percent.

The study of water was extended over a range of temperature from about 0°C to 100°C. The results are shown graphically in Fig. 2. The value of the dielectric constant as a function of temperature is expressed with an accuracy equal to that of the experimental results by the equation

$$\epsilon = 78.54[1 - 0.00460(t - 25) + 0.0000088(t - 25)^2] \quad (2)$$

It is gratifying that these values are in good agreement with those obtained by Drake, Pierce, and Dow (preceding paper) over the range of temperature covered by these observers. They are also in reasonably good agreement with the results of earlier observers given in The International Critical Tables.

We now come to the results obtained on dilute salt solutions where conductivity effects are appreciable. Here the situation is much more complicated and shows (1) that the frequencies corresponding to maximum current in the resonator and maximum reaction on the oscillator are different when the conductivity of the dielectric is appreciable, and (2) that the resonators cannot in general be treated as circuits of lumped capacity, resistance, and inductance.

The evidence to support the above statements comes from the use of resonators, already referred to, containing a hot wire element. These resonators are of the cylindrical type. A small section of the metal loop joining the

Fig. 3.

two cylinders is removed and replaced by a condensite tube of the same size. This serves to hold the two halves of the resonator rigidly in their former position and at the same time to enclose a piece of 40 gauge copper wire which connects the two cut ends of the loop and restores the connection in the circuit. To the midpoint of this wire are welded the ends of two lengths of 40 gauge wire, one copper and one constantan, which enter through the walls of the tube. These form one junction of a thermo-couple, which is a sensitive detector of any current in the resonator. If the resonator is suspended in water and placed at a distance of two feet from the coil of a power oscillator tuned to the right frequency, sufficient heat is developed in the hot wire to give a full scale deflection of a table galvanometer.

With such a resonator it is possible to tune the oscillator to give either maximum current in the resonator or maximum reaction back on the oscillator. As we have already seen, the two settings are identical for water at a frequency of about 6×10^7 ($\lambda = 5$ M.) When, however, we turn to dilute salt solutions at about the same frequency, the two methods of tuning no longer

give identical results. Instead, the frequency required to produce maximum current in the resonator is greater than that required for maximum reaction on the oscillator, and the difference between the two increases with the conductivity of the solution. This is shown by the results given in Fig. 3. The upper curve corresponds to maximum reaction; the lower to maximum current. It should be noted that a power oscillator was used to get settings by the first method, and the small oscillator to get settings by the second method.

Fig. 4. Values of ω_0^2/ω^2 at varying conductivities obtained by the reaction method of determining resonance. Each curve was made with a different resonator. The natural periods in air of the corresponding resonators, expressed in seconds, are: 1, $11.40 \cdot 10^{-2}$; 2, $5.060 \cdot 10^{-2}$; 3, $1.914 \cdot 10^{-2}$; 4, $1.373 \cdot 10^{-2}$.

Such results are not unexpected in a general way. Suppose we have two circuits 1 and 2, 1 being the oscillator and 2 the resonator. We assume that the circuits are coupled inductively, and that the oscillator is subjected to an impressed E.M.F. of amplitude

$$E = e^{j\omega t}$$

Then, if $Z_1 = R_1 + jX_1$ is the impedance 1, $Z_2 = R_2 + jX_2$ the impedance of 2, and M the mutual induction between them, the complex current amplitudes are given by

$$A_1 = E / [Z_1 - (Mj\omega)^2 / Z_2]$$

$$A_2 = A_1 M j\omega / Z_2.$$

In determining the condition for A_2 maximum, we may certainly neglect changes in A_1 , if circuit 1 is a power oscillator. The frequency ω_2 corresponding to A_2 maximum is then seen to be given by the equation

$$\frac{d}{d\omega} \left(\frac{(R_2^2 + X_2^2)^{1/2}}{\omega} \right) = 0. \quad (3)$$

The determination of ω_1 , corresponding to A_1 maximum, is far less simple, but in general we may expect ω_1 and ω_2 to be different. It is suggestive, however to observe that in the case of a resonator of lumped capacity, inductance, and resistance immersed in a non-conducting medium, we may expect ω_1 and ω_2 to be equal. In this case the impedance of the resonator is $R + j[L\omega - (1/C\omega)]$. Conductivity of the dielectric being negligible, R is simply the resistance of the all-metal circuit, and may be neglected in comparison with L and C . ω_2 is then found to be equal to $1/(LC)^{1/2}$. If, on the other hand, we assume that the condition for A_1 max. is governed primarily by the second term in the denominator, we find that ω_1 is also equal to $1/(LC)^{1/2}$, provided we again neglect R in comparison with L and C .

It is, however, as we have pointed out, impossible to regard the resonators as circuits of lumped capacity, inductance, and resistance when conductivity is appreciable. We will now, in conclusion, consider this point. Values of ω_0^2/ω^2 , the apparent dielectric constant, for dilute salt solutions of various concentrations obtained by the two methods of determining resonance

are shown graphically in Figs. 4 and 5. The values obtained by the reaction method are in general higher than those from the thermal procedure and both sets of results vary among themselves. We will discuss only the latter, where the theory is far simpler. These are given in Table II.

Fig. 5. The same, obtained by the thermal method. Corresponding natural periods in air are: 1, $6.629 \cdot 10^{-9}$; 2, $2.495 \cdot 10^{-9}$; 3, $1.914 \cdot 10^{-9}$.

Let us consider the behavior of an ideal resonator of lumped capacity, inductance, and resistance and compare the predictions with the results given above. Such a circuit placed in a conducting dielectric will behave as if the plates of the condenser were short circuited by a resistance r . If R denote the resistance of the metallic part of the circuit as before, and C and L its capacity and inductance, then it can be shown that the impedance of the circuit suspended in the conducting dielectric is

$$R + \frac{r}{1 + r^2 C^2 \omega^2} + j \left(L \omega + \frac{r^2 C \omega}{1 + r^2 C^2 \omega^2} \right).$$

The frequency corresponding to maximum current amplitude in the resonator may be obtained from Eq. (3) and is given by

$$\omega^2 = \frac{1}{2LC} \left(1 \pm \left(\frac{2LC}{r^2 C^2} + 1 \right)^{1/2} \right),$$

provided we neglect the ratio R/r . Now it can be further shown that for any condenser filled with a medium of dielectric constant ϵ and conductivity γ , the equivalent resistance r between the plates is given by

$$rC = \epsilon / 4\pi\gamma.^{13}$$

Therefore, taking account of the fact that $C = \epsilon C_0$, where C_0 is the capacity of the resonator in air, and that $1/C_0 L = \omega_0^2 = 4\pi^2/T_0^2$, where T_0 is the natural period of the resonator in air, we obtain finally

$$\frac{\omega^2}{\omega_0^2} = \frac{1}{2\epsilon} \left\{ 1 \pm \left(1 + \frac{2}{\epsilon} (2T_0\gamma)^2 \right)^{1/2} \right\}.$$

Since if $\gamma = 0$ this must reduce to $\omega^2/\omega_0^2 = 1/\epsilon$, we discard the $-$ sign before the radical. This result may be compactly expressed by

$$\omega/\omega_0 = f(h)/\epsilon$$

¹³ I am indebted to Professor Pierce for this result.

where $f(h)$ has been tabulated for values of h .¹⁴ If $h=0$, $f(h)=1$. If h is less than about 0.12, $f(h)$ is not greater than 1.001, and ω_0^2/ω^2 is equal to ϵ to an accuracy of 0.2 percent or better.

For distilled water where $\gamma = 3 \times 10^6$ e.s.u., approximately, we should be able to express ϵ by ω_0^2/ω^2 to an accuracy of 0.2 percent in the case all measurements for which T_0 (corresponding to ω_0) is less than 10^{-7} secs, or for which λ_0 , the corresponding wave-length in free space, is less than 30M. For liquids, e.g. salt solutions, for which γ is greater, $f(h)$ increases more rapidly with T_0 and we should be obliged to use smaller resonators having higher natural periods. But the main thing to notice is that as $T_0\gamma$ becomes appreciable and increases, ω_0^2/ω^2 becomes increasingly less than ϵ , according to Eq. (4).

If we attempt to correct the experimental values according to Eq. (4), we obtain the results given in the last column of Table II. Now it is pretty clear that these corrected results cannot give the true values of the dielectric constants of the solutions. The reason for this is that if they did, we should be obliged to assume the dielectric constant to vary with the frequency over the range covered by the measurements and to be greater than that of pure water. The results of Drake, Pierce, and Dow, however, show that the dielectric constant of dilute salt solutions is independent of frequency over the range in which we are interested and is in fact the same as that of water to an accuracy of about 1 percent up to a concentration of 1/70 normal KCl. These results are obtained by a method in which the theory is much simpler and the correction factor known. We are therefore justified in concluding that although the resonators may be treated as circuits of lumped capacity, inductance, and resistance in cases where the conductivity of the dielectric is negligible, i.e., where $T_0\gamma$ is small, they do not in general have the properties of such circuits, but behave in a much more complicated way. It is possible indeed that they are rather to be regarded as lines, if of a complicated type. The analysis of the behavior of even the simplest types of lines is, however, very complex under the circumstances of the above measurements and no attempt has been made to carry it out.

In any case, from the experimental results on the salt solutions, it is clear that we can use ω_0^2/ω^2 directly to express ϵ in the case of frequencies determined by the thermal method up to conductivities many times that of water, provided we use resonators having small natural periods. Table II shows that anomalies begin to appear at conductivities corresponding to values of $T_0\gamma$ for which the correction term $f(h)$, obtained from the analysis of the ideal circuit, begins to become significant. This is not unexpected. It appears that we are safe in equating ω_0^2/ω^2 and ϵ for values of h not greater than about 0.1. This means that if we use a resonator having a natural period in air of about 10^{-9} sec, we can employ the method up to conductivities about 100 times that of water. On the other hand if we make settings by the reaction methods we run into difficulties considerably sooner. Here we are probably safe up to conductivities 20-30 times that of water.

ON THE ANOMALOUS ROTATION OF THE SUN*

BY ROSS GUNN

NAVAL RESEARCH LABORATORY, WASHINGTON, D. C.

(Received February 3, 1930)

ABSTRACT

The requirements of Jeans' theory of the anomalous solar rotation are not in accord with the facts of solar magnetism. A new theory is worked out which attributes the anomaly to atmospheric motions arising from the interaction of ions with the solar magnetic field and an assumed electric field. Observations of the solar atmosphere are made only in those regions where the gaseous pressure is such that the ion free paths are long. Ions of both kinds which execute long free paths in crossed electric and magnetic fields are swept in the same direction and give rise to a mass motion. This superimposed drift of the solar atmosphere is shown to account for the rotational anomaly and the calculated variation of the angular velocity with latitude is of the observed form. The theory requires that the sun possess a radial electric field having a sign and distribution similar to that observed on the earth.

IT HAS been known for nearly 100 years that the measured rotational period of the sun depends upon the latitude of the point selected for observation and that it varies from 25 days at the equator to over 30 days at the pole. Moreover, the value of the period at any given place seems to depend somewhat on the level of the point observed. It has been found that in the solar reversing layer the measured angular velocities at low latitudes, expressed in degrees per day, were given approximately by the relation

$$W = 14^\circ.54 - 3^\circ.50 \sin^2 \lambda \quad (1)$$

where λ is the latitude.

Jeans¹ has proposed a theory to account for the rotation phenomena and he attributes the effects to the braking action of the radiation which filters through the outer solar layers. The final form of his theory requires that the central regions of the sun rotate from ten to fifty times faster than the surface layers and that these layers play only a minor part in the transfer of the radiated angular momentum. It is difficult to establish the existence of high rotational velocities inside the sun from theoretical considerations and it now appears that such a rotation may be improbable. The essential characteristics of the solar magnetic field are known from the work of Hale and his collaborators at Mt. Wilson^{2,3} Observatory. This work established the fact that the distribution of the solar magnetic field at any given level was similar

to that of the earth; that the field was limited radially and that the magnetic pole did not coincide with the geographic pole but rotated about it with a period of 31.4 days. These magnetic facts suggest that Jeans' theory of the anomalous solar rotation is incorrect, for if we assume that the rotational velocity changes from layer to layer as we go outward from the core of the sun, then the motion of the magnetic pole with respect to the axis of rotation will set up electrical eddy currents in the moving layers which will tend to bring them into rotational synchronism with the magnetic field. This difficulty would vanish if the magnetic and geographic poles coincided. A still more serious difficulty arises from the fact that on almost any theory of the permanent magnetic field of the sun and earth, as for example, a theory which attributes the field to electrical currents^{4,5}, the magnetic pole would be expected to rotate with the same period as the entire mass. Superimposed on this might be a slow precession but it is unlikely that the solar fields should behave in a manner essentially different from that observed in the case of the earth whose magnetic poles rotate with the period of the entire mass. It thus seems clear that the rotational period of the entire solar mass is 31.4 days and not one-tenth of this as is required by Jeans' theory. The objections to Jeans' theory are of such a nature that the problem has been re-examined. It has been found possible to account for the observations in a simple manner by considering the electromagnetic reactions of the ions in the solar reversing layer.

Mt. Wilson researches demonstrated that the solar magnetic field is essentially similar to that of a uniformly magnetized sphere whose exterior field is limited by some special mechanism. It has been shown that this limitation of the solar field is adequately explained by the diamagnetic properties⁶ of the solar atmospheric ions; for the effective permeability of an ion gas approaches zero under precisely the conditions that exist in the solar reversing layer. It has been argued recently that boundary effects may annul the diamagnetism of the reversing layer, but this view can not be supported. The effect of the boundary has been considered by van Leeuwen⁷ for the case of a metal, who found that the current sheet at the boundary is able to compensate for the volume diamagnetic effect under certain special conditions. She considered the case of short free paths and assumed that the free electrons making up the electron gas were reflected specularly when they collided with the boundary. To meet this condition it is necessary that the boundary be sharp and that the component of the electron momentum normal to the boundary be reversed on impact while the tangential component is preserved. The requirement is satisfied when an electron collides with a heavy ion but when an ion collides with a boundary ion or molecule of its own mass, the normal momentum of the colliding ion is not reversed and boundary currents cannot cancel the volume diamagnetism. Ions play an important part in solar dia-

magnetism and it is clear that van Leeuwen's calculations do not apply there. Moreover, we must note that the sun's atmosphere has no outer boundary and the inner boundary is not sharp so that complete compensation is impossible and we are left with the primary effect—diamagnetism. This general conclusion was pointed out clearly enough in the writer's first paper.⁸ Chapman⁹ has proposed an alternative theory of the radial limitation of the magnetic field but the author has shown¹⁰ that the effect he invokes to explain the phenomena is largely cancelled by another effect which arises from the inhomogeneity of the impressed magnetic field. Moreover, Chapman's theory encounters a serious qualitative difficulty in that the gravitational drift currents of the type he postulates become very small at high solar latitudes where the magnetic field intensity becomes large and nearly parallel to the gravitational acceleration. Thus his theory leads to the conclusion that the magnetic field at a given level near the poles should be much larger than is observed and that a large unobserved stray magnetic field should exist. Diamagnetism on the other hand is equally effective at the poles as at the equator and predicts the same fractional reduction of the initial field at a given ion pressure. This is in accord with observation.

The existence of diamagnetism in the reversing layer and direct spectroscopic evidence both show that the ion free paths in the reversing layer must be longer than the critical free path; that is, they are longer numerically than the radius of the helix generated by the ion as it is caused to spiral about the impressed magnetic field. When this condition is satisfied, other important motions of the nature of ion drifts arise from a combination of an impressed magnetic field with other types of field. These drifts may result from a magnetic field crossed with a gravitational field^{11,12}, an inhomogeneous magnetic field,¹⁰ or an electric field.⁸ The ion drifts and their possible effects have been investigated elsewhere; it is only of importance to note here that the first two effects give rise to ion drifts which are opposite in direction for the positive and negative ions and hence constitute a current while the electric field crossed with a magnetic field acts in such a way as to urge both ions in the same direction and hence is of the nature of a mass movement. When the free paths of the ions and electrons are both longer than their respective critical free paths both drift in the same direction with the same velocity. In certain unobserved regions of the solar atmosphere, however, the free paths of the electrons are longer than their critical radius while the free paths of the ions are less than their own critical value. Thus in this special region electric currents flow which may tend to magnetize or demagnetize the sun according to the direction of the impressed electric field. Such currents may be important in theories of sunspots or of the limitation of the solar magnetic field,

but it is to be noted that the conductivity of this narrow region is moderately large and any electric field must necessarily be small. Our greatest interest in the present paper is in the mass motions of the atmosphere and we therefore assume the sun to have electric as well as magnetic fields and will consider their joint mechanical effects. At the solar equator the direction of the magnetic field is tangential and that of any electric field must be radial. These crossed fields give rise to an equatorial ion drift which is in the same direction for both types of ions and is independent of the charge or mass of the ion. Were neutral molecules present they would presumably be swept along by occasional collisions with ions. It thus seems possible that the observed anomalous rotation of the sun is an effect arising from the movement of the solar atmosphere and is not due to deep seated circulation which seems to be required in earlier ideas regarding the phenomena.

The problem of the electrical state of a rotating heavenly body has been considered by several writers^{13,14,15} and the electrical charge distribution worked out under special assumptions. For example, Rosseland¹³ has pointed out that in the stars loss of charge by radioactive processes might be expected. In addition we may have electrical fields arising from a separation of charge due to (a) gravitational fields¹⁶ (b) temperature gradients (c) radiation pressure (d) pressure gradients¹³ (e) motion in a magnetic field.¹⁵ It seems probable that in the reversing layer (a), (b), and (c) are small compared to the electric fields arising from other causes. A study of the electric fields arising from the motion of the earth in its own magnetic field has been made by Page¹⁵ who assumed that the earth was a uniformly magnetized conducting sphere. Upon working out the consequences of his assumptions he found that electric fields are set up in the high atmosphere which have values such that the ions are swept to the westward with a velocity of the same order of magnitude as the peripheral velocity of the earth. An observer outside the earth watching the ions in the high atmosphere would thus observe an apparent rotational period greater than 24 hours. The entire calculation may equally well be applied to the sun and correction made for the change of magnitude of the quantities due to a larger field and a different type of magnetic distribution. This readjustment does not greatly alter the situation and if the sun is assumed to be unchanged as a whole and free of electric fields in the reversing layer, except those arising from the solar rotation, then an observer on the earth watching an equatorial point in the reversing layer would observe a period of rotation for the layer which is greater than the period of rotation as indicated by the motion of the magnetic pole. This is not in accord with observation and we must conclude that radial electric fields other than that due to rotation in its own magnetic field exist in the solar reversing layer. We shall not enter into a discussion as to the origin of this electric field but simply point out that observation demands its existence. Moreover, as we

¹⁶ Pannekoek, *Bull. Astro. Inst. Netherlands* 19, (1922).

shall see presently, the electric field required is in the same direction, is much smaller, and varies radially in substantially the same manner as the observed electric field of the earth. It is thus consistent with such astrophysical data as are available at the present time.

The mean drift velocity u imposed on both kinds of ions which execute long free paths in crossed electric and magnetic fields is given by

$$u = \frac{E \times H}{H^2} = \frac{E}{H} \sin \beta. \quad (2)$$

Where E and H are in e.m.u. and β is the angle between E and H . We will take H positive northward in the reversing layer at the equator since it coincides in direction with the rotational velocity of the sun and E radially outward. Under this condition a positive value of u corresponds to a westward velocity relative to the surface. According to Mt. Wilson data^{2,3} the magnetic field H at a given atmospheric level and latitude λ is given by

$$H = H_0(1 + 3 \sin^2 \lambda)^{1/2} \quad (3)$$

where H_0 is the value of the equatorial field at the level considered. Thus combining (1) and (2) the superposed angular velocity ω at a given level which arises from the velocity of drift is

$$\omega = \frac{E \sin \beta}{H_0 R [(1 + 3 \sin^2 \lambda)(1 - \sin^2 \lambda)]^{1/2}} \quad (4)$$

where R is the radius of the sun. The diamagnetic layer of the solar atmosphere distorts the permanent magnetic field and the value of β is not readily determined. It is convenient to note that due to diamagnetism the magnetic field is nearly parallel to the surface of the sun in a region 30° on each side of the equator (say) and that the electric field must be radial, so that within the range specified an expansion of Eq. (4) is valid and we may also set $\sin \beta = -1$. Making this substitution, expanding (4) and retaining only the first two terms we have

$$\Omega = \Omega_0 - (E/H_0 R)(1 - \sin^2 \lambda) \quad (5)$$

where Ω is the resultant (observed) angular velocity, Ω_0 the angular velocity as measured by the rotation of the magnetic pole and the last two terms represent the contribution due to the atmospheric drift. In order to account for faster rotation at the equator we must now assume that the required value of E is radially inward or negative. If we set

$$\Omega_0 + (E/H_0 R) = \Omega_0' \quad (6)$$

then (5) becomes

$$\Omega = \Omega_0' - (E/H_0 R) \sin^2 \lambda \quad (7)$$

and agrees in form with the observed relation given in Eq. (1). By selection of the correct value for E ; Eq. (7) gives the exact relation. Thus from Eq. (1) and (7)

$$(E/H_0R) = 7.06 \times 10^{-7} \text{ rad/sec}$$

and taking $R = 6.95 \times 10^{10}$ cm and $H = 25$ gauss we find $E = 0.013$ volts/cm.

There are no data available which contradict the assumption of a radial electric gradient of 0.01 volt/cm in the observed regions of the reversing layer and unless the atmosphere of the sun rotates slower than the magnetic poles we must assume that some kind of an electric field exists which is directed radially inward. The conductivity of the layer in the direction of the electric field has been shown to approach zero⁸ when the electric and magnetic fields are nearly perpendicular as they actually are in the equatorial zone we have considered. There is therefore no reason to suppose that electric charges can readily flow in such a manner as to neutralize the field. Near the poles the electric and magnetic fields approach parallelism and the conductivity increases; thus the electric field distribution in this region is quite different from that at the equator.

The previous calculation of the equatorial electric field was made for an observed level where the magnetic field was taken as 25 gauss. At different values of the magnetic field we might expect different values for the drift velocity. Observations show that deviations do exist but they are not so large that it would be legitimate to assume the electric field constant at all altitudes. A better approximation is suggested by the fact that the drift velocity is observed to be nearly constant with superposed regular variations. On this assumption we have

$$(E/H) = K_1 = 5 \times 10^4 \text{ cm/sec} \quad (8)$$

which requires that E increase with increasing ion pressure in the same manner that H is known to increase. This relation undoubtedly breaks down in the deeper layers of the solar atmosphere. The origin of the electric field is unknown and the distribution cannot now be calculated from independent considerations. The required distribution can be worked out, however, by use of Eq. (8) and earlier results obtained from diamagnetic considerations¹⁰ which gave an approximate relation between the ion density and the magnetic field in the reversing layer. This relation is:

$$N = H^2 / 4\pi kT \quad (9)$$

where N is the ion density, H the magnetic field intensity, k the Boltzmann constant and T the absolute temperature. By the use of observed values for H it was found that the distribution of N was a logarithmic function of the altitude. Making the further assumption that the solar atmosphere was in gravitational equilibrium it was found that the distribution calculated from magnetic data agreed with that required by a gravitational equilibrium distribution when the mean atomic weight of the particles in the reversing

layer was taken as 3.3. A correction for the presence of an electric field was also made but the calculation is not now believed to be valid. In view of the recent work of Unsöld¹⁷ it hardly seems legitimate to talk of equilibrium in the solar atmosphere but if the values of the ion pressure are averaged over a fairly long period the usual expression probably well represents the distribution. On this assumption the ion density n at any level r is given by

$$n = n_0 \exp \left(\frac{-zm_H g(r-R)}{kT} \right) \quad (10)$$

where n_0 is the number of ions per cm^3 at the "surface" of the sun, z the mean atomic weight of the solar ions and R the radius of the sun. We will follow earlier work and assume that the surface of the sun is located at a level where the free paths of the ions are just equal to the radius of the helix generated by an electron as it is caused to spiral about the impressed magnetic field. Extrapolation has shown that the ion pressure at the surface so defined was nearly one half an atmosphere and that the magnetic field intensity was roughly 12,000 gauss. Below this surface the magnetic field is no longer modified by diamagnetism and the electric conductivity is so large that electric fields are negligibly small compared to those outside. Combining (9) and (10) we have

$$H = H_0 \exp \left(\frac{-zm_H g(r-R)}{2kT} \right) \quad (11)$$

where H_0 is the surface magnetic field intensity. We are now able to calculate the difference of potential between the solar surface and outer space. Let this potential difference be ϕ , then from Eq. (8) we have

$$\phi = \int_R^\infty E dr = K_1 \int_R^\infty H dr. \quad (12)$$

The integration is carried out along a path radially outward at the equator which gives by aid of Eq. (11)

$$\phi = \frac{2K_1 H_0 kT}{zm_H g}. \quad (13)$$

Taking therefore $K_1 = 5 \times 10^4$ cm/sec; $H_0 = 1.2 \times 10^4$ gauss; $Z = 3.3$; $m_H = 1.66 \times 10^{-24}$ gm; $g = 2.7 \times 10^4$ cm/sec²; $k = 1.37 \times 10^{-16}$ and $T = 6 \times 10^3$ we get $\phi = 6.6 \times 10^{15}$ e.m.u. or 6.6×10^7 volts. We have pointed out that in the special region where the electron free path is long and the ion free path is short (according to our special definition) the conductivity is moderately large and the electric field must therefore be small. If we assume that the electric field in this region is zero and integrate from the outer edge of the region where H_0 is 280 gauss⁴ out to infinity we find the potential difference to be 1.5×10^6

¹⁷ Unsöld, *Astrophys. J.* 69, 209 (1929).

volts. This is nearly the same potential difference as is observed between the earth and free space. While this calculation cannot be exact since it involves a questionable extrapolation of what may be considered an empirical relation it probably does give a good approximation to the potential difference required to maintain an electric field of the assumed type and distribution.

Special attention should be called to the striking similarity between the the solar magnetic and electric fields and the same fields on the earth. Spectroscopic data show that the solar magnetic field is not unlike that of the earth except for the distortion of the field due to diamagnetic effects in the reversing layer. The requirements in regard to the electric field as deduced in this paper from the observed movements of the solar atmosphere are almost identical with the observed features of the earth's electric field. The earth's electric field in the region of poor electrical conductivity is radially inward, its value drops off with decreasing pressure fairly rapidly in a manner precisely as required in the sun. Moreover the observed potential difference between the surface of the earth and its outer layers is almost identical with that calculated for the sun. The equality of the potentials of the sun and earth seems significant, for conditions on the sun and earth are greatly different and such equality could hardly be expected unless the electric fields arise from the same fundamental mechanism.

A SIMPLE EQUATION FOR THE JOULE-THOMSON EFFECT IN REAL GASES

BY JAMES A. BEATTIE

RESEARCH LABORATORY OF PHYSICAL CHEMISTRY, MASSACHUSETTS INSTITUTE OF TECHNOLOGY

(Received February 1, 1930)

ABSTRACT

Simple approximate relations are given for μC_p and the pressure variation of C_p expressing these quantities as functions of the independent variables p and T . They are derived from the usual thermodynamic relations by use of one form of the Beattie-Bridgeman equation of state, which expresses V as an explicit function of p and T . The values of the Joule-Thomson coefficient μ for air and for ammonia calculated from the relations for μC_p and C_p , equations (10) and (4) respectively, agree well with the observed values in the case of air, and fairly well for ammonia.

The approximate equation for μC_p calculates values of the inversion temperatures of the Joule-Thomson effect in air which are in good agreement with the experimental results.

A VERY sensitive test of an equation of state is the accuracy with which the calculated values of the Joule-Thomson coefficient μ and of the inversion temperatures of the Joule-Thomson effect, at which $\mu = 0$, agree with the experimental results. Keyes¹ has shown that the Joule-Thomson effect in air and carbon dioxide can be calculated by use of his equation of state with good success.

Bridgeman² has derived expressions from the general thermodynamic relations and the Beattie-Bridgeman³ equation of state for μC_p and for the pressure variation of the heat capacity at constant pressure, C_p . The values of μ and of C_p for air computed from these relations agree well with those obtained by Roebuck⁴ from Joule-Thomson measurements which extend from 0 to 280° C and to 220 atmospheres. The equation of state constants used by Bridgeman in this correlation were determined from the compressibility data of Holborn and Schultze.⁵

The values of μ and of the pressure variation of C_p for ammonia calculated⁶ from the expressions obtained by use of the Beattie-Bridgeman equation of state agree well with the experimental results of Osborne, Stimson, Sligh and Cragoe⁷ at the higher temperatures, but the deviations become large at the

⁷ Osborne, Stimson, Sligh and Cragoe, Scientific Papers of the Bureau of Standards **20**, 65 (1925).

lower temperatures. The equation of state constants for ammonia used in this comparison were determined from the compressibility measurements of Meyers and Jessup,⁸ which Cragoe⁹ and Osborne, Stimson, Sligh and Cragoe⁷ have shown could be correlated, in part, with the thermal data. The large deviations of the values computed by use of the equation of state from the experimental results at the lower temperatures may be due to either or both of two causes: A slight inconsistency between the thermal and compressibility data, or the failure of the equation of state to reproduce all of the trends of the compressibility data near the saturation line. It should be mentioned, however, that the equation reproduces the compressibility measurements of Meyers and Jessup with an average deviation of 0.043 percent.

The equation of state used for these calculations is:

$$p = \frac{RT}{V} + \frac{\beta}{V^2} + \frac{\gamma}{V^3} + \frac{\delta}{V^4} \quad (1)$$

$$\beta = RTB_0 - A_0 - Rc/T^2$$

$$\gamma = -RTB_0b + A_0a - RB_0c/T^2$$

$$\delta = RB_0bc/T^2$$

where R is the ideal gas constant and A_0 , a , B_0 , b and c are constants for each gas.

The expressions for μC_p and the pressure variation of C_p used by Bridgeman² and by the author⁶ can be derived from the usual thermodynamic relations by use of (1). They are:

$$\mu C_p = \frac{\left[-B_0 + \frac{2A_0}{RT} + \frac{4c}{T^3} \right] + \left[2B_0b - \frac{3A_0a}{RT} + \frac{5B_0c}{T^3} \right] \frac{1}{V} - \frac{6B_0bc}{T^3V^2}}{1 + \frac{2\beta}{RTV} + \frac{3\gamma}{RTV^2} + \frac{4\delta}{RTV^3}} \quad (2)$$

$$C_p = C_p^* - R + (Rc/T^3V) [6 + (3B_0/V) - (2B_0b/V^2)] + \frac{R \{ 1 + [B_0 + (2c/T^3)](1/V) + [-B_0b + (2B_0c/T^3)](1/V^2) - (2B_0bc/T^3V^3) \}^2}{1 + (2\beta/RTV) + (3\gamma/RTV^2) + (4\delta/RTV^3)} \quad (3)$$

where C_p^* is the value of C_p at infinitely low pressures and is a function of the temperature alone. These equations will be called the "complete" relations, since no approximations have been introduced.

Equation (3) can be transformed¹⁰ into the "approximate" expression:

$$C_p = C_p^* + [(2A_0/RT^2) + (12c/T^4)]p; \quad (4)$$

⁸ Meyers and Jessup, *Refrigerating Engineering* 11, 345 (1925).

⁹ Cragoe, *Refrigerating Engineering* 12, 131 (1925).

¹⁰ Beattie, *Phys. Rev.* 34, 1615 (1929).

in which the independent variables are p and T . This relation represents the heat capacity data on air and ammonia almost as well as the "complete" equation (3).

By use of a suitable approximation,¹¹ the equation of state (1) can be written so that V is expressed as an explicit function of p and T :

$$V = \frac{RT}{p} + \frac{\beta}{RT} + \frac{\gamma}{R^2 T^2} p + \frac{\delta}{R^3 T^3} p^2 \quad (5)$$

where β , γ and δ are the functions of the temperature and the equation of state constants given in (1). When the values of the equation of state constants determined for use in equation (1) are substituted into (5), the experimentally measured volumes are calculated very satisfactorily even to 100 atmospheres or over when the temperature is not too near the critical value.

Equation (5) makes it possible to express μC_p and C_p as functions of the independent variables p and T . When the partial differentials in the general thermodynamic relations

$$\mu C_p = T \left(\frac{dV}{dT} \right)_p - V \quad (6)$$

$$\left(\frac{dC_p}{dp} \right)_T = -T \left(\frac{d^2 V}{dT^2} \right)_p \quad (7)$$

are evaluated by (5), and equation (7) integrated between 0 and the variable pressure p , there result:

$$\mu C_p = \left[-B_0 + \frac{2A_0}{RT} + \frac{4c}{T^3} \right] + \left[\frac{2B_0 b}{RT} - \frac{3A_0 a}{R^2 T^2} + \frac{5B_0 c}{RT^4} \right] p - \left[\frac{6B_0 b c}{R^2 T^5} \right] p^2 \quad (8)$$

$$C_p = C_p^* + \left[\frac{2A_0}{RT^2} + \frac{12c}{T^4} \right] p + \left[\frac{B_0 b}{RT^2} - \frac{3A_0 a}{R^2 T^3} + \frac{10B_0 c}{RT^5} \right] p^2 - \left[\frac{10B_0 b c}{R^2 T^6} \right] p^3 \quad (9)$$

It has been shown¹⁰ that the heat capacity of air and ammonia are fairly well represented by the relation (4) which can be obtained from (9) by dropping all terms of higher powers than the first in p . When a similar approximation is made in (8), we obtain a relatively simple equation for μC_p in terms of the variables p and T :

$$\mu C_p = \left[-B_0 + \frac{2A_0}{RT} + \frac{4c}{T^3} \right] + \left[\frac{2B_0 b}{RT} - \frac{3A_0 a}{R^2 T^2} + \frac{5B_0 c}{RT^4} \right] p. \quad (10)$$

The comparisons of the values of μ computed by use of the "approximate" equations (10) and (4) with the experimental results for air and ammonia are given in Tables I and II. For these computations the values of C_p^* for air were calculated by use of (4) from the equation¹²

$$C_p = 0.2405 + 0.000019t$$

¹¹ Beattie, Proc. Nat. Acad. Sci. 16, 14 (1930).

¹² Holborn, Scheel and Henning, "Wärmetabellen". Vieweg, Braunschweig, 1919; p. 58.

where C_p is the specific heat capacity at one atmosphere in 15° calories per gram per degree centigrade and t is in degrees centigrade; the values of C_p^* for ammonia are given by the expression⁷

$$C_p^* = 1.1255 + 0.00238T + \frac{76.8}{T}$$

where C_p^* is in joules(v) per gram per degree centigrade and T is in degrees Kelvin ($^{\circ}\text{C} + 273.1$).

The units of the equation of state constants and those in which the data are expressed are given in the Tables I and II. In the use of equation(4) the reduction factors calculated from data given in International Critical Tables for the term evaluated from the equation of state are: 0.83605 15°-calories/gram per liter-atmospheres/mole for air, and 0.101293 joules (v) per cm^3 -atmospheres for ammonia. The values of C_p derived from (4) were then multiplied by the following reduction factors before use in (10): 1.19609 liter atmospheres/mole per 15° calories/gram for air and 7.5030 cm^3 -meters of mercury per joules (v).

TABLE I. Comparison of the calculated with the observed values of the Joule-Thomson coefficient for air.

Calculations made with Equations (10) and (4).

In units of atmospheres, liters per mole and degrees Kelvin ($T^{\circ}\text{K} = t^{\circ}\text{C} + 273.13$) the values of the constants for air are:

$$R = 0.08206, A_0 = 1.0763, a = 0.01697, \\ B_0 = 0.04070, b = -0.02174, c = 12 \times 10^4.$$

Mol. wt. = 28.960.

Observed values are those of Roebuck.

Temp. °C		0	25	50	75	100	150	200	250	280

	obs.-calcd.	-36	-24	-14	-8	-3	-4	5	4	2

The calculated values of μ for air (Table I) agree well with those derived from Roebuck's⁴ data, except at the lowest temperatures, where there are reasons² to believe that the measured values may be in error. The average

deviation of the values calculated by use of the "approximate" relations (10) and (4) is 0.005, whereas Bridgeman² found that the average deviation resulting when the "complete" relations (2) and (3) are used is 0.0035.

TABLE II. *Comparison of the calculated with the observed values of the Joule-Thomson coefficient for ammonia.*

Calculations made with Equations (10) and (4).

In units of atmospheres, cm³ per gram and degrees Kelvin, the values of the constants for ammonia are $R=4.81824$, $A_0=3000$, $a=51.5$, $B_0=0.45$, $b=131$, $c=360 \times 10^6$.

Observed values are those of Osborne, Stimson, Sligh and Cragoe.

				-12.92	1.475	6.19	1.06
				-18.22	0.394	6.81	.98

The "approximate" equations (10) and (4) lead to values of μ for ammonia (Table II) which are in fair agreement with the experimental results above 30° but in poor agreement at the three lowest temperatures. The same remark⁶ may be made concerning the values calculated by the "complete" equations (2) and (3) with the exception that the agreement is somewhat better throughout. The average deviation for all values at and above 30° C is 0.19 for the "approximate" equation and 0.08 for the "complete."

It is of interest to find out how well the "approximate" relation represents the inversion temperature of the Joule-Thomson effect. This is determined by placing $\mu C_p = 0$, and from (10) we obtain

$$p = - \frac{-B_0 + (2A_0/RT) + (4c/T^3)}{(2B_0b/RT) - (3A_0a/R^2T^2) + (5B_0c/RT^4)} \quad (11)$$

for the relation between the pressure and the inversion temperature. For zero pressure the inversion temperature can be obtained from the relation:

$$-B_0 + \frac{2A_0}{RT} + \frac{4c}{RT^3} = 0. \quad (12)$$

In Figure 1 is given a comparison of the calculated inversion temperature for air determined from (11) by use of the constants given in Table I with the values which Roebuck⁴ derived from his measurements. Figure 1 is a reproduction of Figure 11 of Roebuck's paper with the curve determined by

(11) added. The curves of the inversion temperatures obtained by use of van der Waal's and Dieterici's equations are taken from Roebuck. Comparison of our Figure 1 with Figure 1 of Bridgeman's paper² which gives

Fig. 1. Inversion temperatures of the Joule-Thomson effect in air.

the curve of the inversion temperatures derived from the "complete" equation shows that the values obtained from the "approximate" equation agree with Roebuck's points as well as those calculated from the "complete" equation.

LETTERS TO THE EDITOR

Prompt publication of brief reports of important discoveries in physics may be secured by addressing them to this department. Closing dates for this department are, for the first issue of the month, the twenty-eighth of the preceding month; for the second issue, the thirteenth of the month. The Board of Editors does not hold itself responsible for the opinions expressed by the correspondents.

Atomic Oxygen as a Reducing Agent

The reducing action of hydrogen peroxide on certain metallic oxides is well known and the analogous reaction might be predicted for atomic oxygen. The authors have spent a considerable amount of time in this laboratory trying to obtain a reducing action by exposing various metallic oxides to a beam of oxygen atoms produced in the electrodeless discharge. No reaction was obtained except in the case of molybdenum trioxide where a reaction was obtained which appears to be identical with the reaction produced by atomic hydrogen. A target which has been covered with a finely divided deposit of molybdenum trioxide, which is light yellow in color, shows the characteristic slate blue trace where the oxygen beam impinges. Not only were traces of atomic hydrogen and atomic oxygen beams produced side by side on the same target, but beams of atomic hydrogen and atomic oxygen were impinged on the same spot in alternation. No change in the appearance of the blue discoloration could be observed on changing from the oxygen to the hydrogen beam, which seems to eliminate the possibility that the reaction with oxygen is the formation of a higher oxide.

Elaborate precautions were taken to free the oxygen from all impurities including water. In order to make certain of the active species the beam was passed through an inhomogeneous magnetic field. The central undeviated line characteristic of atomic oxygen (Phipps and Kurt, Phys. Rev. **34**, 1357, 1929) was readily obtained but no trace of side lines was observed. This is probably due to lack of intensity since the side lines should be fainter than the central line. It may be that the oxygen atom only reacts with the trioxide when it is in the 3P_0 state or it may be of course that the active species is not the atom but an activated molecule, the $^1\Sigma$ state for instance. It should be noted that the molybdenum trioxide is reduced only when it is separated by two slits from the discharge. If only one slit is used or the target is introduced into the discharge the blue coloration disappears almost instantly.

A Generalization of the Rydberg Formula

On the basis of the old quantum theory it was known that by carrying on a perturbation calculation one arrived successively at the Rydberg and then the Ritz formulas for the terms of a hydrogen-like atom. In the quantum mechanics it has been shown by Hartree (Proc. Camb. Phil. Soc. **24**, 1929) that for an atom with one electron in a central field a generalized Ritz formula holds at least for large values of N . This formula can be written (the series limit is here taken as the zero of frequency).

$$\nu_n = R / (n + \sum_{i=0}^{\infty} q_i \nu_n^i)^2. \quad (1)$$

The ordinary Ritz formula is the approximation obtained when only the first two powers (0 and 1) of ν_n are used. To use more than two constants q_0 and q_1 would make the formula unwieldy and would scarcely help in the complicated cases while in the simpler cases additional constants are unnecessary. The two-constant formula of Ritz is however wholly inadequate to describe certain series of terms especially in the complex atoms.

If one follows the perturbation calculation of the quantum mechanics to two approximations admitting the possibility of more than one optical electron, one is led to suggest a substitute for the Ritz formula which has sometimes important advantages and in the other cases reduces to the Ritz expression. The theoretically derived energy equation can be put into the simple form:

$$\nu_n = R / \left[n + \sum_i p_{in} / (\nu_i - \nu_n) \right]^2 \quad (2)$$

This form involves perhaps a slightly artificial but quite harmless definition of the term for which $i=n$ —so that the first approximation (i.e. Rydberg correction) is taken into account without spoiling the appearance of the formula. For all other terms the ν_i are by no means arbitrary constants but are the observable spectroscopic terms. These as well as the properties of the p_{in} will be described in detail elsewhere. For the present only two remarks will be made.

I. In the most usual case there will be no term difference, ν_i with $p_{in} \neq 0$ small enough to be important. That is, all the terms in the sum can be expanded in powers of ν_n and the ordinary Ritz formula results if one uses only the first two terms in the expansion.

II. If there is more than one electron a possibility arises which has heretofore been left out of account. An electron configuration not belonging to a particular series may have

an energy level for which $\nu_i - \nu_n$ changes sign with varying n while the corresponding p_{in} 's are not zero. The conditions for such a case are too complicated to be described in the present letter further than to say that they are stringent enough to explain why this case is not more common than it is found to be. In the neighborhood of such a ν_i the terms will be given by

$$\nu_n = R / [n + q_0 + P / (\nu_i - \nu_n)]^2 \quad (3)$$

and will show a remarkable irregularity which was first observed by Schrödinger (Ann. d. Physik 77, 1925).

This case which arises, e.g. in Pb I, Ca I, Hg I, Al II, Si III, etc. is possibly the most common form of irregularity and in the past has invariably led to misidentification of terms. If one takes the theory into account and reassigns quantum numbers accordingly the applicability of Eq. (3) is obvious. The term ν_i is incidentally located and because of the conditions on p_{in} is fairly definitely identified.

The chief contribution of this work is the satisfaction one gets from the elimination of an apparent flaw in our notions of line spectra. It permits a temporary relief from the feeling that our present theory is not complete enough.

The Reflection of Hydrogen Atoms From Crystals of Lithium Fluoride

The work on the reflection of hydrogen atoms is now being extended to a study of the reflection from LiF crystals. These crystals were grown from the melt by a modification of the method of Ramsperger and Melvin, (Jour. Opt. Soc. 15, 359, 1927). A freshly cleaved surface was mounted in the apparatus formerly used in the study of the reflection from NaCl and KCl, (Frank. Inst. 206, 301, 1928), and bombarded with a sharply defined beam of hydrogen atoms issuing from a discharge tube.

Under favorable conditions the reflection in the specular beam from LiF was as high as 50% of the incident beam, as compared with 5% from NaCl, and 0.5% from KCl. As in the case of the other alkali halides which have been studied, the specularly reflected beam

from LiF is confined to within the same angular breadth as the incident beam.

During the course of the investigation some peculiar fan-shaped patterns consisting of a central spot with radial streamers appeared on the molybdenum oxide coated detecting plate. Simultaneous with the appearance of these patterns the LiF crystal lost its atomic reflecting power and acquired a brownish tinge similar to what is usually observed on glass when bombarded by ions or electrons. If the copper crystal holder was maintained at +110 volts with respect to the surrounding case, these patterns disappeared. Furthermore, it was found that when the crystal holder was insulated similar patterns appeared on the plate even though the crystal was removed from the holder. It was therefore dem-

onstrated that these patterns were due merely to the electrostatic repulsion of the ions in the beam by the charge which accumulated on the crystal and the crystal holder. By applying an electric field across the beam to remove the ions, the fan-shaped patterns disappeared, the crystal remained clear, and its high reflecting power persisted for a long time.

With the discovery of this effect of ion bombardment on the reflecting power of LiF it became of interest to make a reinvestigation of the reflecting power of NaCl and KCl with

the ions removed from the beam. The reflection from these crystals, however, appeared to be unaffected by the ion concentrations present.

The fact that the electrostatic charging of an insulated surface can deflect a beam of ions into irregular patterns, shows that one must be cautious in interpreting any pattern as the diffraction of de Broglie waves when ions or electrons are reflected from insulated crystals.

THOMAS H. JOHNSON

Multiple Coincidences of Geiger-Müller Tube-Counters

The ordinary method of coincidences [e.g. Bothe and Kolhörster, *Zeits. f. Physik* 56, 751 (1929)] does not make possible the performance of experiments upon the individual very high energy β -particles which presumably give rise to the coincidences between Geiger-Müller tube-counters (*elektronenzählröhre*), chiefly because suitable collimation by slits is nearly impossible in the interesting region of very high energies (10^8 to 10^9 volts) which this new instrument has opened to analytical experimental attack. It occurred to the writer some weeks ago that the observation of the coincidences between *three* tube-counters would make such a study possible. The first two counters would serve as a slit-system, defining a beam and "picking out" individual particles to be observed while the third movable counter would serve to detect these particles after being scattered, deflected by a magnetic field, or otherwise subjected to experimental conditions. Experiments are under way here for obtaining information on the probability of deflection of such extremely fast β -particles in various (small) angles in passing through a scattering block. The theory of multiple scattering indicates that the deflections may be below the practical limits of angular resolution, but even an upper limit, experimentally determined, for such extremely fast particles will be of interest. Other applications are readily devised.

This arrangement has another advantage which may be immediately appreciated—that of increased "resolving power" against accidental coincidences. If the resolving power of the means for determining coincidences between two tube-counters is such that say one out of 200 (residual) counts (a practical

figure) in each individual tube-counter will be accidentally "coincident" within the specified range of resolution, the probability of such an accidental coincidence of *three* tube-counters within the same range of resolution is 1 out of 40,000. The idea of the *multiple*-coincidence method using a series of counters is an obvious extrapolation. Theoretically, any desired degree of freedom from accidental coincidence can readily be obtained, provided, of course, that the efficiency of counting is 100 per cent, as has been shown to be approximately true for β -particles. We do not yet have sufficient data to say how nearly true this is for the very fast particles with which we are dealing. Scattering deflections of the primary particle at the walls of the counters or in the air between counters will set an ultimate limit on the resolution which can be reached in practice even with perfect counting. Secondary effects may also be of importance. The actual resolving power will be less than that calculated on a probability basis also by reason of true coincidences produced only in part of the series of tube-counters by particles not capable of passing through the whole series. There is no doubt, however, that enormously increased resolving power can be obtained by the requirement of multiple instead of paired coincidences. The attainment of very great freedom from accidental coincidences is of greatest importance when it is desired to reduce the solid angle subtended by the tube-counters for true coincidences to a small figure, because of the large number of residual counts in comparison to those due to the very small intensity of the penetrating radiation. The possibility of using the multiple-coincidence method as the basis of a "gamma-ray tele-

scope" for exploring small areas of the sky is being investigated. The intensity of the penetrating radiation is very low for such a purpose if the definition of really small areas is desired unless, of course, later observations show the penetrating radiation to come from particular small areas of the sky rather than uniformly from all directions. An estimate hazarded on the basis of present data, assuming uniform intensity per unit solid angle, gives as the order of magnitude one true coincidence per 1,000 minutes for counters of cross-section 50 cm², subtending one square degree in the sky. Automatic recording of the amount of the penetrating radiation coming from particular areas of the sky, using two tube-counters and a special "coincidence circuit" somewhat similar to that recently published by Bothe [Zeits. f. Physik, 59, 1 (1929)] was begun here early last November. The resolving power (for our circuit between 0.005 and 0.001 second) of such an arrangement without *multiple* coincidences constitutes a severe limitation on the smallness of the area which can be observed.

A few practical notes on a brief oscillographic study of the recovery-time of a tube-counter and associated amplifier-circuits under various conditions may be of interest to others who are using the instrument. The high resistances (5×10^9 ohms) used by Geiger and Müller and others require the tube-counter to operate at a variable voltage, since the time-constant of the circuit is even larger than the average time between counts, whereas lower resistances restrict the range of voltages which give satisfactory counting. By connecting the central wire of the tube-counter directly

to the grid of the amplifier-tube, the recovery-time of the tube-counter may be observed. Oscillograms have been taken using this circuit with resistances from 1 to 5,000 megohms. The recovery-time increases rapidly as the voltage is raised above the minimum critical voltage at which counts begin (which is the same for all values of R), and varies by a factor of perhaps five for different single counts at any given voltage. The average recovery-time (to within five volts of the initial potential on the central wire) varies from perhaps 0.002 second at a voltage midway in the working range (of only a few volts) for $R=1$ megohm, to two seconds or more for $R=5,000$ megohms, where the true working range (actual voltage between central wire and tube) is considerably more than 100 volts. In spite of this very long recovery time of the tube-counter itself, however, a 0.00004 μ f blocking condenser between the tube-counter and the amplifier-grid, and a grid-resistance of 10 megohms, as used by Bothe, gives satisfactory counts on the first amplifier-tube up to several hundred per minute, and the recovery-time of this amplifier-tube is of the order of 0.001 second. The oscillograms using this arrangement show that of two counts 0.01 second apart the second one will be usually missed, but counts 0.1 second apart give ample impulses (UX201A tubes were used). These results could have been safely inferred, but perhaps some interest may be attached to their demonstration by oscillograms.

Temperature Shift of Spectral Lines and Pole Effect in Vacuum Arc

The work of many investigators has shown that the wave-length of most emission lines is a linear function of the total pressure acting when the vapor is in an arc, a furnace, or an absorption tube. It has been considered that the pressure shift per atmosphere is independent of the temperature. This implies that the experimental wave-length of a line from a source operating at constant pressure is independent of temperature. The chief purpose of this note is to report experimental evidence indicating that this view may be incorrect.

Two conclusions may be drawn from previous work: (1) that the wave-length of a line under given conditions of temperature

and pressure is, at least for low values, independent of the partial pressure of the vapor, and (2) that ionic density plays a small part, if any, in the phenomenon of pressure shift. The first is justified by the conclusion of Babcock¹ that pressure shift is independent of changes in vapor density. The second may be justified by consideration of the results of King² and of Füchtbauer, Joos, and Dinkelacker.³ King found a larger pressure shift per

¹ Babcock, *Astrophys. J.* 67, 240 (1928).

² King, *Astrophys. J.* 35, 183 (1912).

³ Füchtbauer, Joos, and Dinkelacker, *Ann. d. Physik* 71, 204 (1923).

atmosphere in the furnace than Babcock¹ found for the same iron lines in the arc. The value of the mean ratio for the pressure shift of lines common to the two lists is 2.3 with an average deviation of 0.3. The second paper reports pressure shifts for $\lambda 2537$ of mercury in absorption at room temperature. These results indicate that molecular density, while not the ultimate cause, is probably the controlling factor in pressure shift.

An increase in pressure at constant temperature indicates an increased density of molecules. This change usually causes an increase in wave-length. A decrease in temperature at constant pressure might be expected to operate similarly.

The core of an iron arc of the Pfund type with cathode below is surrounded by a rather thick envelope of iron vapor and iron oxide dust. In an effort to establish the existence of a temperature shift a layer of this envelope was used by the author as a low temperature source of iron lines, while the central section of the arc with polarity reversed was used as a high temperature source. Two of the three lines selected for this test showed a shift in the direction indicated above, and of the right order of magnitude.

In order to check these results plates were taken of $\lambda 5890$ of sodium. Shifts measured between four different types of sources gave results qualitatively in agreement with that indicated by the previous paragraph. It is considered that neither line asymmetry nor fine structure, as reported by Minkowski⁴ and Schüler⁵ respectively, can account for all the experimental data as easily as the hypothesis here suggested.

⁴ Minkowski, *Zeits. f. Physik* 55, 16 (1929).

⁵ Schüler, *Naturwiss.* 16, 512 (1928).

It therefore seems possible to measure, by means of this phenomenon, effective flame, arc, and furnace temperatures when the pressure is known. Assuming that the wave-length of a line is a linear function of the number of molecules per unit volume, that ionic fields of high value were absent from the sources of Babcock and King, and that the effective temperature of King's furnace was 2000°C , the calculated temperature of the effective emission point of Babcock's iron arc for the lines common to both lists is $5000^{\circ}\text{C} \pm 700^{\circ}\text{C}$.

St. John and Babcock⁶ found that a 6 mm iron arc was practically free from pole effect at pressures below 10 cm. However, an anomalous behavior of the yellow sodium lines has been reported by Kiess.⁷ Both lines showed a shift of 0.004A between absorption in a low pressure tube and emission in a vacuum arc at 6 cm pressure. This indicates either that the pressure shift is non-linear at low pressures or that a positive pole effect existed in the arc used. Two sets of plates of $\lambda 5890$ taken by the author showed a positive pole effect of 0.005A and 0.006A respectively in a carbon arc operated at about 10 cm pressure. Therefore it is suggested that care be used in applying this result of St. John and Babcock to any conditions other than those investigated by them.

All plates were taken at Yale University.

Emission of Positive Ions From Thoriated Tungsten

In an earlier note, it was reported that tungsten when heated gave off positively charged tungsten ions. The emission from thoriated tungsten has been investigated and in addition to tungsten ions of mass 184, thorium ions of mass 232 and an ion of mass 247 ± 2 have been obtained. This latter ion may be thorium monoxide, although all attempts to reduce it with H_2 have failed. It appears at an estimated temperature of about

2300°C . The alternative explanation is that it is some other extremely stable compound or an element. An x-ray investigation of various thorium sources is under way to settle this last possibility.

BOOK REVIEWS

Hydro-und Aeromechanik, Vol. 1. O. TIETJENS. Nach Vorlesungen von L. Prandtl. Pp. 238, figs. 178. Verlag von J. Springer, Berlin, 1929. Price RM 15.

This is a well-written introduction to the Hydro and Aerodynamics of inviscid fluids. The first section, which deals with topics that are of importance in aerostatics, is pleasing to the reader as it opens with brief sketches of the early work of Euler and Stevin on the pressure of fluids and then contains a particularly clear presentation of the statics of the atmosphere and the effect of different atmospheric conditions upon the behavior of a balloon. The section closes with an account of the phenomena of capillarity.

The second section is devoted to the kinematics of liquids and gases. It is pointed out that vortex-lines, stream-lines and paths of particles are not the only lines of kinematical importance because experiments in which foreign matter is introduced into the fluid at some point to render the motion visible have directed attention to the streak-lines (Streichlinien). A method of constructing streak-lines is explained and illustrated by means of diagrams. The section also contains a presentation of the geometry of vector fields and special attention is paid to the kinematical boundary conditions; in particular, the flow near the points of stagnation is discussed in an illuminating way and it is emphasized that liquids and gases are not ideal but only *quasi-continua*.

Section three deals with the dynamics of inviscid fluids and includes important applications of Bernoulli's Equation and Potential Motions. The chapters on vortex-motion and the influence of compressibility are particularly striking and should be of great help to the student who wishes to master the particularly fruitful methods by which Ludwig Prandtl has rejuvenated the science of Hydrodynamics.

H. BATEMAN

La Nouvelle Mecanique des Quanta. GEORGE BIRTWISTLE. Pp. vi+333. Paris, Librairie Scientifique Albert Blanchard, 1929.

This French translation of Birtwistle's book, "The New Quantum Mechanics" is hardly likely to be of much interest to American physicists. The English original¹ was a hasty compilation of the results of the new methods in atomic physics which was useful for reference in regard to formulas although it contributed scarcely anything toward a clear understanding of the theory. The French edition has four appendices by the translators, M. Ponte and Y. Rocard, amounting to 30 pages giving brief accounts of Dirac's relativistic electron theory, the revised electron theory of metals, fluctuations in the new statistics and the so-called "hydrodynamic" interpretation of wave mechanics.

E. U. CONDON

¹ Reviewed in Phys. Rev. 33, 869 (1929).

The Terminology of Physical Science. DUANE ROLLER. Pp. 115, demy 8 vo. Paper cover. University of Oklahoma Press, 1929. Price \$1.00.

Readers of text-books and research reports, and listeners to lectures and recitations are often irritated by non-conformity in the choice of words or in pronunciation. The booklet under review voices the irritation of one such reader and listener. The reviewer sympathizes with the author's state of mind but doubts the feasibility of his proposed reform by proclamation. The chance of success would be greater in this case if the author had not made blunders in etymology, shown little understanding of differences between synonyms, and used his non-scientific English inexpertly. The reader may also be shocked by the author's readiness to

recommend wide departures from standard usage and by his propensity for log-rolling in favor of his colleagues.

In spite of obvious faults of presentation the monograph should prove interesting and stimulating to members of that small group of physicists who wish to improve the intelligibility of their science. The fragmentary remarks on non-technical terms and on technical terms used in half a dozen other sciences are outside the scope of this review.

L. W. McKEEHAN

PROCEEDINGS
OF THE
AMERICAN PHYSICAL SOCIETY

MINUTES OF THE NEW YORK MEETING, FEBRUARY 21 AND 22, 1930

The 162nd regular meeting of the American Physical Society was held in New York City at the Physics Laboratories of Columbia University on Friday and Saturday, February 21 and 22, 1930. The presiding officers were Professor Henry G. Gale, President of the Society, Dr. W. F. G. Swann, Vice-President, Professor John Zeleny and Dr. Arthur E. Ruark.

The Saturday morning session was given over to a Symposium of Photoelectric and Thermionic Phenomena. The speakers were F. L. Mohler, F. K. Richtmyer, William V. Houston, C. E. Mendenhall and G. Wentzel. The titles of their papers appear in the following list of abstracts, numbered 46-50 inclusive. The symposium was attended by over 400 persons.

At the regular meeting of the Council held on Friday, February 21, 1930 twenty-two were elected to membership. *Elected to Membership*: Eugene C. Bingham, Kenneth C. Blanchard, Willard E. Bleick, Leo P. Delsasso, A. M. I. A. W. Durnford, Frank M. Exner, Charles F. Ffolliott, D. A. Fogelsanger, Omer R. Fouts, James D. Hardy, Mituyosi Igari, A. L. Johnson Jr., Wendell R. Koch, Richard H. Lee, William G. Moran, Yoshio Nishina, Luhr Overton, Elmer N. Turnquist, J. S. Webb, Herman G. Wehe, Donald B. Woodbridge and Oliver R. Wulf.

The regular scientific session consisted of 63 papers, Numbers 1, 2, 3, 8, 14, 15, 20, 32, 33, 42, 57 and 58 were read by title. The abstracts of these papers are given in the following pages. An *Author Index* will be found at the end.

W. L. SEVERINGHAUS
Secretary

ABSTRACTS

1. Transient earth currents accompanying the recent Newfoundland earthquake of 1929. RICHARD HAMER, *Acadia University*.—It does not seem to have been recorded hitherto that transient electric and magnetic disturbances were associated with earthquakes. It seems certain that such did accompany the recent earthquake off Newfoundland. Observations, similar or related, of others, besides personal, have been reported supporting the author's contention. The geophysical importance of such a fact is obvious. Several years ago the author proposed to account for variations of the earth's magnetic elements by assuming circulating earth currents. This granted, earth movements would obviously be accompanied by transient electron readjustments. However other possible causes exist; such as temporary readjustments of the electric activity of large mineral deposits and certain strata; also the possible frictional electricity generated due to the relative motion at the long break; and also polarization from fracture or piezoelectric effects on variations of stresses. By induction if not by conduction the temporary

influence of such electrical disturbances was transmitted with a speed approaching that of light in an expanding area around the epicenter. Ordinary seismic waves followed arriving later and later relatively at more distant regions. Thus the author determined the epicenter. The importance of studying earthquakes from this new angle is emphasized.

2. A modification of Wiechert's experiment. T. R. WILKINS AND J. A. WOOD, *University of Rochester*.—Wiechert's single equation method for a direct determination of the speeds of corpuscles has been modified by using a vacuum tube oscillator and an electrostatic deflecting field. This revives an experiment, theoretically very attractive but which has been experimentally extremely difficult. (See J. J. Thomson—Conduction of Electricity through gases.) Since the period of the oscillator can be held very constant, the difficulties experienced by earlier experimenters who used Tesla Coils and large high frequency currents to energize the deflecting fields disappear. The method would seem equally applicable to positive ray analysis or as a general corpuscular filter.

3. Polar molecules—their contribution to energy loss. F. HAMBURGER JR., *Johns Hopkins University*, (Introduced by J. B. Whitehead).—Some discussion has taken place during the last year as to the possible effects of molecular orientation as a source of dielectric loss. The suggestion has been offered that even at frequencies as low as those of commercial power circuits the theory of molecular orientation may be offered as an explanation of at least a portion of the dielectric loss. This paper is an attempt to examine this suggestion on the basis of the Debye theory and the available experimental data. It shows that in the case of glycerine at temperatures of zero and ten degrees Centigrade the loss due to orientation, at frequencies below ten thousand cycles per second, is negligible. Furthermore, it indicates that for the usual insulating oils, the possibility of accounting for even a portion of the dielectric loss observed at commercial frequencies, on the basis of molecular orientation, is remote.

4. Magnetoresistance and elastoresistance in permalloy. L. W. MCKEEHAN, *Yale University*.—A continuation of preliminary work reported by Arnold and McKeehan (Phys. Rev. [2] 23, 114 (1924)). The effect of intensity of tensile stress upon the change in resistance due to magnetization has been observed in straight wires of annealed permalloy over a wide range in composition. Additional studies have been made on specimens containing 45, 77 and 84 percent nickel. In these latter wires the magnetization and resistance have been measured simultaneously. The resistance for a given magnetization is not single-valued, although a symmetrical "hysteresis" loop on the magnetization-resistance plane may cross itself. The magnetic fields were produced by long solenoids and the magnetic field intensity did not exceed 50 gauss in the definitive experiments. Under suitable conditions, however, this field intensity is sufficient for approximate saturation of the magnetoresistance effect. The results lend support to the view that adjacent atoms in a pure ferro-magnetic metal, and—a fortiori—in a ferromagnetic alloy, differ widely in those constraints which determine their dirigibility by externally applied forces.

5. Stabilized oscilloscope with amplified stabilization. FREDERICK BEDELL AND JACKSON G. KUHN, *Cornell University*.—One stage of amplification included in the stabilizing circuit of the Bedell-Reich oscilloscope, which comprises a cathode-ray tube with linear time-axis for observation of periodically varying quantities, extends the range of frequencies through which the curves on the screen of the cathode-ray tube may be stabilized and maintained stationary so that they can be photographed either with camera or contact print. Linearity of time-scale is shown by equality of successive wave-lengths and is controlled by an equalizing adjustment. Although not primarily intended for use beyond the audio range, the instrument has in this way been stabilized above 100,000 cycles. Curves are given showing the use of the instrument for the study of electrical quantities, as in the study of modulation and rectification, the ripple voltages in B-eliminators and filters and the wave-form of different oscillators; also curves obtained with photo-electric cell, showing flicker in candle-power in light sources, and curves, obtained with condenser microphone, showing wave-form of notes from musical instruments, the violin and clarinet. To be published in Review Scien. Instruments, April, 1930.

6. The initial stages of electrical breakdown. J. W. BEAMS AND J. C. STREET, *University of Virginia*.—A Kerr cell method (Beams, *Jour. Franklin Inst.* **206**, 809, (1929)), a simple comparison arrangement and a method making use of a rapidly rotating mirror (Beams, *Phys. Rev.* **33**, 1086 (A) (1929) have been used to determine the average time lag of the spark. The last method has also been used to photograph the different stages of the discharge. The time lag is decreased by ultra-violet light on the cathode, ions in the gap or by increasing the field strength. When a field of 4×10^4 volts/cm is very suddenly impressed, in ordinary air at atmospheric pressure containing the usual number of ions the average time lag is less than 5×10^{-8} sec. In dry filtered air, at atmospheric pressure, from which as many ions as possible were removed by auxiliary fields, 6×10^5 volts/cm could be applied for over 10^{-6} sec. without breakdown. Similar results were obtained with dry filtered hydrogen and nitrogen. Brass ball electrodes were used. The velocity of expansion of the spark is increased with decrease of pressure. At atmospheric pressure, the luminosity near the cathode becomes the most intense in approximately 2×10^{-7} sec. and gives rise to the well-known streamers. However at pressures roughly from 0.008 mm to 0.001 mm the anode luminosity was found to be the most intense.

7. Some new types of electrical discharge in high vacua. R. W. WOOD, *Johns Hopkins University*.—Discharges excited in such high vacua as to be called non-conducting in the usual sense, excited through external electrodes with high frequency oscillators of wave-lengths varying from two to thirty meters. The effects of electric and magnetic fields upon the curious luminous balls and spindle shaped bodies (which have been named "plasmoids" provisionally) have been exhaustively studied, as well as the curious red phosphorescence of the glass which usually appears. Some progress has been made towards the explanation of these discharges by employing stroboscopic methods. The remarkable pressure changes which occur in the sealed off tubes as a result of "clean-up" or gas-evolution have been followed by vibrating quartz fiber mano-meters.

8. Complete dissociation of H_2 . E. U. CONDON, *University of Minnesota*.—It is well known that where nuclear motions are involved mere energy sufficiency does not always make possible processes of excitation by electron impact or light absorption. Usually the critical potential in molecular hydrogen near 30 volts is interpreted as $H_2 \rightarrow H^+ + H^+ +$ two electrons for which the energy needed is $4.4 +$ twice $13.5 = 31.4$ volts. But this cannot be since if both electrons be removed the nuclei possess a mutual potential energy of about 18 volts. Therefore this process should require about 50 volts and when it occurs the protons formed would have kinetic energy of about 9 volts each. Just as Condon and Smyth (*Proc. Nat. Acad.* **14**, 871 (1928)) have interpreted the 11 volt dissociation as due to transitions from the normal state to the repulsive Heitler-London potential energy curve so now it is suggested that the loss at 30 volts is due to transitions from the normal state of H_2 to the repulsive Morse-Stueckelberg curve of H_2^+ in which case the process produces protons having about 6 volts of kinetic energy.

9. The primary ions formed by electron impact in hydrogen. WALKER BLEAKNEY AND JOHN T. TATE, *University of Minnesota*.—The results of a study of the primary products of ionization in hydrogen obtained with a mass spectrograph previously described (*Phys. Rev.* **34**, 157 (1929)) indicate that there are at least three different processes by which an ion may be formed by a single impact with an electron. (1) The molecular ion H_2^+ appears at 15.4 ± 0.1 volts as the result of the removal of one electron. (2) Ionization and dissociation occur simultaneously, yielding the atomic ion H^+ at a minimum potential of 18.0 ± 0.2 volts. (3) At about 30 volts another ion is formed, presumably H^+ , which is characterized by the fact that it has several volts kinetic energy. It appears in the analyzer as a very broad peak and it also has been found to reach a side plate against the influence of a retarding field. The reactions (2) and (3) are much less probable than (1). These effects find a theoretical interpretation in the potential energy curves of Morse and Stueckelberg for the hydrogen molecule, as Condon has pointed out in the preceding paper.

10. The reflection of hydrogen atoms from crystals of lithium fluoride. THOMAS H. JOHNSON, *The Bartol Research Foundation*.—The reflection of hydrogen atoms from crystals

studied at first with NaCl and KCl crystals is now being extended to other alkali halides. The preliminary results with lithium fluoride are interesting in two respects. In the first place a sharply defined specular beam appeared as with the other alkali halides heretofore tried but LiF may, under favorable conditions, reflect up to about fifty percent of the incident beam in the specular direction as compared with 5 percent for NaCl and 0.5 percent for KCl. In the second place it has been found that the reflecting power of LiF is strongly affected by the action of the atomic hydrogen or other products of the discharge tube which is used as the source of the atomic beam. Thus it has been found that a crystal at room temperature, though exposed to atmospheric air and to the molecular hydrogen from the unexcited discharge tube for some time, reflected the atomic beam intensely at first but the reflection had fallen off to one half of its initial intensity in a time of the order of one minute. At higher temperatures the same fatigue occurred but the reflection persisted for longer times up to about an hour.

11. Molecular beams in electromagnetic fields. D. E. OLSHEVSKY, *Yale University*.—A systematic synthetic study of possible arrangements of the vector quantities characteristic of a molecular beam experiment such as field strength, field gradient, molecular moment, velocity of beam and force is made. Known experimental arrangements of Kallman-Reiche, Stern-Gerlach, Rabi and of Clark are thus classified and their features clearly brought out. Analysis yields several new experimental arrangements of interest. Briefly, they are: (a) Reversal of beam direction in Rabi's experiment, the last slit being in the magnetic field and beam coming out of the field, with expected improvement in resolution; (b) Arrangement of field gradient at right angles to field and beam direction with possibility of detecting molecules oriented perpendicular to field; (c) Arrangement with the second slit consisting of two closely spaced, field producing wedges, the beam perpendicularly to the plane of the slit. Arrangement (c) seems to be particularly efficient due to the fact that the beam can be left larger than slit spacing, the second slit serving as a highly efficient microscopical field-producing unit.

12. Recombination of hydrogen-like atoms. E. C. G. STUECKELBERG AND PHILIP M. MORSE, *Princeton University*.—The probability that an electron moving with a velocity of V volts recombines with a hydrogen ion or with an ion having a similar field and resultant nuclear charge Ze to form an atom in a state defined by the quantum numbers n, l is usually expressed by the effective cross section of recombination $q(n, l, Z, V)$ cm². The transition probabilities have been calculated from the matrix elements referring to the two states. A solution of the Schroedinger equation in a Coulomb field giving at large distances a plane wave has been found by Mott and by Temple. With the aid of this function an exact expression for the q 's has been obtained, which decreases monotonically with increasing V . For V small compared to $-E_{n,l}$ (the term value) an asymptotic formula can be used of the form $q(n, l, Z, V) = 1.237 \times 10^{-10} \cdot e^{-4n} \cdot C_{n,l} \cdot Z^2/V$. The values for $C_{n,l}$ have been computed for $l=0$ and $n=1, 2$ and 3 ; for $l=1$ and $n=2$ and 3 . $C_{n,l} \cdot e^{-4n}$ decreases for increasing n and approaches 0 for $n = \infty$. For some of the states the exact expressions for any V have been computed. They show in order of magnitude as well as in functional behavior a fair agreement with the older theories and the experiment. However, this theory can not explain the experiments by Barnes and Davis and it seems that their results must be due to a more complex reaction than simple recombination.

13. A search for critical potentials for electron recombination with Hg^+ . A. M. CRAVATH, (*National Research Fellow*), *Princeton University*.—The discovery by Davis and Barnes (Phys. Rev. **34**, 152 (1929)) that electrons which have just enough energy to ionize He^+ recombine astonishingly rapidly with He^{++} suggested a search for recombination of 10.4 volt electrons with Hg^+ . A cylindrical ring electrode 0.6 cm long, 2.5 cm diameter, was placed in a large Hg vapor arc, pressure 0.01 mm, ions per cm³ up to 1.5×10^{11} . Electrons from a small oxide coated filament along the axis of the cylinder were accelerated in the thin sheath around the filament and then travelled out radially through the nearly equipotential ionized vapor to the cylinder whose potential was positive to the filament but negative to the space. The effect sought was a sharp reduction in the electron current reaching the cylinder when the electron energy passed through 10.4 volts. No effect was found. This may be due to the narrow-

ness to the range of energies for which recombination has a high probability, only a fraction of the electrons in the stream from the filament ($T \sim 1000^\circ\text{K}$) having energies in this range. If this range had been comparable in width to the peaks in Davis and Barnes' experimental curves practically the whole electron stream would have been stopped.

14. Sorting the variables in the crystal structures of certain chromium-nickel alloys. F. C. BLAKE AND JAMES O. LORD, *Ohio State University*.—Microphotographs of certain chromium nickel alloys containing from 63 to 85 percent chromium revealed three phases present. The melts were made in a partial vacuum in crucible of alumina and were practically free from carbon. It was noted in general that after the power for the furnace was shut off but the partial vacuum maintained that the vacuum increased showing that some of the residual gases were being absorbed by the melt. Examination revealed nitrogen present in the melt. One phase was readily found to be body-centered chromium. Further experimentation revealed another phase to be chromium nitride and by the use of proper etching reagents a third phase was found to be chromium nickelide, Cr_2Ni , with ninety-six atoms to the unit cell, the cell consisting of four interpenetrating lattices of nickel with four other interpenetrating lattices of chromium, the lattice being body-centered tetragonal with $a = 10.64\text{\AA}$ and with an axial ratio of 1.040. The density of the tetragonal phase is identical with that of body-centered chromium, viz. 6.93. Both the nickelide and the nitride are very hard and practically insoluble in hot aqua regia, especially the nitride. The lattice of chromium nitride was proved to be close-packed hexagonal with $a = 2.751\text{\AA}$, the axial ratio being 1.605, the unit cell consisting of two atoms of chromium and two of nitrogen. This gives a calculated density for chromium nitride of 7.75. The space group for the nitride is D_3^2 with the two nitrogen atoms interpenetrating. The possibility of a fourth phase being present is discussed.

15. An interesting case of a unit lattice made up of interpenetrating lattices. F. C. BLAKE, *Ohio State University*.—Some of the most interesting and important cases of alloys and solid solutions can be studied only by the powder method, for with several phases present no method has yet been devised for obtaining large single crystals of the phases separately. Indeed the importance of many of the alloys industrially is due to the very fact that their crystallinity consists only of microcrystals. Thus the powder method is the only one available. After considerable effort spent more or less uselessly trying to guess at the structure of a tetragonal chromium nickelide a deliberate attempt was made to see if one could build up synthetically a series of interpenetrating lattices of chromium and nickel which would give the reflection intensities observed. This was found to be possible, the lattice consisting of thirty-two atoms of nickel and sixty-four of chromium and having the property of unusual hardness spoken of by Professor W. H. Bragg (Proc. Royal Inst. XXVI, 6 (1929)) for many-atomed lattices of alloys of copper with aluminum, zinc and tin. The most interesting property of such a lattice is that the first sixteen lines that one might expect to be strong on the powder photograph do not appear at all, in agreement with observation. The space-group of the lattice found is D_{10}^4 , a hemihedral form.

16. The classes of symmetry possible in crystals of elements. R. H. CANFIELD, *Naval Research Laboratory, Anacostia, D. C.* The object of this study is to determine the types of space-lattices possible in crystals composed of atoms of one kind and subject only to mutual central forces, the force between two atoms being zero for only one value of the distance. It is found that the conditions of equilibrium of one atom require that the center of gravity of any group of atoms which lie on the surface of a sphere shall lie at the center of the sphere. This condition of what may be termed "barycentric symmetry" limits the possibilities to 21 out of the 32 recognized classes of symmetry. Equilibrium against a generalized infinitesimal strain of the whole crystal imposes the condition that the principal axes of inertia of all such spherical groups of atoms shall have the same directions, and the principal moments of inertia be in the same proportion. This limits the possible classes still further to the five classes of the cubic system. It is concluded that since there are many exceptions to the latter rule many crystals even of elements cannot be regarded as homopolar in the sense of the first paragraph.

17. Excitation potential of the $L\alpha$ satellites of Ag (47). S. W. BARNES AND F. K. RICHTMYER, *Cornell University*. A precise knowledge of the excitation potentials of satellites should make it possible to distinguish between the Wentzel-Druyvesteyn theory of their origin and the so-called "two-electron jump" theory proposed by one of the present authors. The very meagre data in existence indicate that the excitation potentials of satellites are of the order of 20–40 percent higher than those of the corresponding parent lines. Using a Siegbahn vacuum spectrograph and a transformer-kenotron-inductance voltage supply which gave a ripple of much less than one percent, a series of exposures were made at 7, 6, 5, 4.5 and 4.4 kilovolts, respectively, on the $L\alpha$ line of Ag(47), the excitation potential of which is 3.35 k.v. Satellites were clearly visible on the plates taken at 4.5 k.v. and higher, but were not visible on the plate taken at 4.4 k.v., although the intensity of the parent line on the 4.4 k.v. plate was greater than on that at 4.5 k.v. However, the $L\alpha$ line at 3.8 k.v. shows an unsymmetrical "foot", which may indicate the presence of an unresolved satellite structure. If so, the excitation potential of the satellites may be much lower than 4.4 k.v. Acknowledgment is made of assistance from the Heckscher Research Council of Cornell University.

18. Satellites of $K\alpha$ for the elements Ni(28) to As(33). F. K. RICHTMYER AND E. RAMBERG, *Cornell University*.—The satellites $K\alpha_{3,4}$ of the line $K\alpha$ have been recorded previously from Na(11) to Zn(30) at which point they seemed to disappear. At Zn(30) the N shell begins to grow, which fact, it was previously thought, might be in some way related to the disappearance of the satellites. However, exposures made to bring out the satellite structure of the $K\alpha$ line of the elements Ni(28) to As(33) show that satellites (unresolved on the photographic plate) are clearly visible up to As(33), although they are relatively much less intense than for elements of lower atomic number. Observations by means of the two-crystal spectrometer show that the satellites $K\alpha_{3,4}$ of Cu(29) are clearly resolved into the two components, as is found by the photographic method for lower atomic numbers. These new data fit the Moseley type of graph for satellites proposed by one of the authors (F. K. R., *Phil. Mag.* 6, 76 (1928)). Acknowledgment is made of assistance from the Heckscher Research Council of Cornell University.

19. Position and width of the modified line of the spectrum of scattered x-rays. F. L. NUTTING, *The Drexel Institute, Philadelphia*.—The Compton Shift $\delta\lambda = h/mc(1 - \cos\phi)$ was tested at definite, large scattering angles by two independent methods. (a) *Photographic method*. Using fluorescence radiation before and after for fiducial marks, Mo radiation was scattered at 169 degrees from paraffin for 300 hours (maximum spread of scattering angle 12.5 degrees). The mean value of the shift of the center of gravity of the $K_{\beta\gamma}$ line on microphotometric curves gave $h/mc = 0.0231\text{\AA} \pm 0.00023\text{\AA}$. The shift of the peak of the β line (corrected for the presence of the γ line of 1/7.7 its intensity) gave $h/mc = 0.02376\text{\AA} \pm 0.00023\text{\AA}$. (b) *Ionization method*. Using two narrow cylindrical Mo tubes side by side and a Soller slit to increase intensity and scattering at 170 degrees from graphite (maximum spread of scattering angle 8 degrees), the mean of a large number of runs gave $h/mc = 0.0240\text{\AA} \pm 0.00024\text{\AA}$ for the shift of the K_{α} doublet. *Components*. No definite evidence of components appeared in the mean microphotometric curve, although the fluorescence α doublet was clearly resolved and the angular spread of scattering small.

20. The quantitative application of the irregular doublet law to an isoelectronic sequence. R. A. SAWYER, *University of Michigan*, AND J. E. MACK, *National Research Fellow, University of Minnesota*.—Heretofore the irregular doublet law of x-ray spectroscopy has been applied in isoelectronic sequences only qualitatively. (i.e. $\nu(n, l_1) - \nu(n, l_2)$ is a linear function of Z). Now Wentzel's result $\sigma_1(n, l+1) - \sigma_1(n, l) = 0.58 \cdot 2^{1/2}n$ for the first order screening number σ_1 in x-rays is applied, determining the rate of dependence of the energy of the transition $2s^2 2p^4 \leftarrow 2s 2p^5$ upon the atomic number Z in the fluorine-like sequence, to be $49 \cdot 10^8 \text{ cm}^{-1}$. New experimental results in Na III and Mg IV show it to be $48.01 \cdot 10^8 \text{ cm}^{-1}$. Although such accurate predictions are not generally possible for an arbitrary number of electrons, certain regularities may be used for interpolation in many cases.

21. The quantum theory of x-ray exposures on photographic emulsions. A. P. H. Trivelli, *Eastman Kodak Co.* (Introduced by L. A. Jones.)—The quantum theory of photographic exposures as proposed in 1922 by L. Silberstein had to be given up on account of the fact that the differences in sensitivity of the grains are determined not only by the projective area of the grain; a chemical factor is also entering into it for visible radiation. Kinoshita and Th. Svedberg have showed that every α -particle hitting a silver halide grain makes it developable. The sensitivity of the grain is, therefore, determined by its projective area and the probability that a grain is made developable by exposure to α -particles is given accurately by the equation, $p = 1 - e^{-na}$ (a = projective area, n = number of α -particles). An investigation with L. Silberstein has shown that the same equation holds for x-ray exposures.

22. A theoretical and experimental study of the resonance radiometer. J. D. HARDY, *Johns Hopkins University.* (Introduced by A. H. Pfund.) The voltage sensitivity limit of steady deflection galvanometers, regardless of degree of magnification or precision of manipulation, has been shown to be of the order of 10^{-9} volts. This is the natural sensitivity limit set by the Brownian fluctuations in the suspended system causing a random zero unsteadiness. The calculation has been made for the case of the resonance radiometer (See Abstract of A. H. Pfund, *Science* Feb. 1929) and the results show that this natural limit has been lowered by about one hundred times, that is, to the order of 10^{-11} volts, in the present apparatus with a possibility of still further lowering the limit by mechanical and electrical improvements. Some results are given to show that without much precaution a sensitivity surpassing that heretofore obtainable can be realized and one that is very close to the theoretical limiting value. The smallest energy difference that has been with certainty distinguished is of the order of 10^{-4} ergs per second per square millimeter. A method is described for measuring the speed of response of thermocouples. The average speed of the thermocouples used was found to be 0.2 sec. in air and 2 minutes in vacuum.

23. High dispersion in the infra-red. R. BOWLING BARNES, *Johns Hopkins University.*—For the purpose of comparing the Raman effect with infra-red absorption spectra, the following organic liquids have been measured from 3.1μ to 3.6μ : benzene, toluene, ortho-, meta- and para xylene, ethyl-, butyl-, monochlor-, and monobrombenzene. The spectrometer employed an echelette grating, which had 3600 lines per inch, and which concentrated the energy of a Nernst filament into the region which was investigated. The dispersion of the instrument was such that with the slits each 0.25 mm in width, one "slit width" was approximately $25A^\circ$. The calibration was obtained in terms of the positions of the 5461 line from an auxiliary Hg arc, and the wave-lengths as given are considered accurate to $\pm 0.003\mu$. In every case the bands in this region, due to the C-H vibration, which have hitherto been reported only under low dispersion have been resolved into many component parts. The 3.25μ band of benzene was resolved into three equally strong components lying at 3.231, 3.253 and 3.291μ respectively. The shifts of these bands caused by the various substitutions were studied, and in no case was a shift of over 0.01μ found. Published data on the Raman effect failed to reveal the complexity shown by these absorption spectra.

24. Iodine fluorescence in the infra-red. F. W. LOOMIS, *University of Illinois.*—Oldenberg has photographed in the infra-red the fluorescence spectrum of iodine excited by the mercury arc. The spectrum is chiefly an extension of the well-known series of doublets excited by the green mercury line; but in the neighborhood of the infra-red doublets there appear other lines. Pringsheim attributes these to transitions to the extraordinary new molecular level which he reported. It is now found, however, that they disappear when the yellow lines are filtered from the light of the mercury arc. They should therefore be attributed to the higher members of the fluorescence series excited by the yellow lines. The relatively high intensities of these members is due to their being on the right arm of the Franck-Condon parabola.

25. The relation between Raman spectra and the molecular structure of organic compounds. DONALD H. ANDREWS, *The Johns Hopkins University.*—The following procedure is

proposed for identifying the type of vibration in the molecule to which an observed frequency in a Raman spectrum corresponds. It is assumed that the only forces acting between the atoms in the molecule are those produced by the chemical bonds, and that there is a restoring force if the bond is stretched or if the angle which the bond makes with the other bonds on an atom is altered from the normal equilibrium value. It is also assumed that all non-polar chemical bonds have the same force constants. The different frequencies observed in the Raman spectra may then be considered as due solely to the variation in mass of the atoms concerned and to their space relation to each other, that is, whether they are in a straight chain, a branching chain, a ring, etc. It is possible to calculate in this way the number of Raman lines which should be observed for any compound, and the frequencies they should have. There is fair agreement with the observed spectra, close enough so that the lines can be identified with different types of motion in the molecule, and calculations of specific heat can be made.

26. A theory of zodiacal light. E. O. HULBURT, *Naval Research Laboratory*.—Since solar outbursts which give rise to aurorae and magnetic storms also cause changes in the zodiacal light it is possible that the zodiacal light is mainly sunlight re-emitted by the absorbing particles and not scattered or reflected by them. This permits a reconsideration of an old view that the particles originate in the earth's atmosphere, although the 15 percent polarization of the zodiacal light is left unexplained. Neutral atoms and molecules of the upper fringe of the earth's daytime atmosphere upon collisions of the second kind are ejected upward with velocities around 11 km sec^{-1} to 30,000 or 80,000 km levels where they are ionized by the solar ultra-violet light. Under the action of gravitation, the earth's magnetic field and the pressure of solar radiation, an oblong ring of ions and electrons is formed around the earth in the plane of the ecliptic, the ion densities being fairly low, below 10^3 cm^{-3} ; this gives rise to the zodiacal light. The ring is perhaps 50,000 km distant on the daylight side of the earth. On the night side the ring stretches out to great distances 10^5 or 10^6 km. At its far end ions continually stream away in the direction of the sun's rays, so that the ring merges into a sort of comet's tail which may be the Gegenschein. Quantitative estimates are made throughout which depend on apparently acceptable assumptions of light pressure, time of ionization, etc. The estimates suggest a rate of escape of the earth's atmosphere of perhaps 10^6 ions $\text{cm}^{-2} \text{ sec}^{-1}$, or about 10^{-6} of the atmosphere in 10^6 years.

27. A recording interferometer. C. W. CHAMBERLAIN, *Michigan State College*.—Light from a broad slit, illuminated by an incandescent filament, is collimated and divided into two parts which travel separate paths, one variable in length. The beams are reunited, with their wave fronts parallel, passed through a Wadsworth or constant deviation prism, and viewed through a telescope focussed for infinity. With eyepiece removed circular Fizeau fringes are seen in monochromatic light, when the interfering paths are unequal. With the eyepiece in position, a new type of interference system in white light is brought into view. The continuous spectrum is crossed by sharp dark bands whose positions in the spectrum correspond with the wavelengths for which the interference system is opaque, or the path difference is an odd number of half wave-lengths. The number of bands appearing in an octave is identical with the path difference of the interfering beams, measured in terms of the longest wave. Lines appearing in that portion of the spectrum between 5016 and 6678 of helium correspond to a linear movement of one ten thousandth of a centimeter. In a similar manner, a range of spectrum may be arranged such that a change of one line in the range corresponds to a movement of five hundred-thousandths of an inch or any desired decimal part of an inch or centimeter.

28. An interference method of measuring distance. STUART H. CHAMBERLAIN, *Michigan State College*. (*Introduced by C. W. Chamberlain*).—A collimated beam of white light is divided into two parts, slightly separated and converging toward a mirror, at a distance to be determined. The returning beams, slightly diverging, are received by an interference system which renders them parallel and permits lateral and linear displacements of the parallel wave fronts. The beams are passed through a prism and viewed through a telescope focussed for infinity. A dual system of interference bands is formed; one serviceable for accurately adjusting the

instrument to receive the returning beams, the other to measure the distance between the light source and the distant mirror. The distance is determined by the number of dark bands appearing in a continuous spectrum. The new method substitutes a portable base line measured in wave-lengths of light and an interference method of determining the angle subtended by this base line at the distant mirror for the present method of measuring by means of angles and a fixed base line.

29. On the question of aberration of the light from terrestrial sources and its application to the experiment of Esclangon. N. GALLI-SHOHAT, *Mount Holyoke College*.—The definition of the "relative" ray in the classical ether-theory is usually given by means of two small openings through which light passes. The question is how to direct the moving telescope (two openings)—one system—in order to observe the light traveling along a wave normal in the other system (ether). A more careful analysis of this definition from the standpoint of the cinematics of the question gives the result that the direction of the ray actually observed depends upon the orientation in space, the angle x representing the aberration of light from terrestrial sources being $\beta^2/2 \sin 2\theta_0$, [$\beta^2 = (v^2/c^2)$, $\theta_0 = (\theta_0, v)$]. This method of construction of the relative ray when applied to the experiment of Esclangon gives a satisfactory explanation of the effect observed. The curve calculated for this case, using for the declination of the apex δ 68° , coincides with that given by Esclangon and the values of the right ascension, α and the velocity v of the apex came out as $\alpha = 20^h$ and $v = 200$ km/sec in agreement with modern astronomical data. This second order aberration should also give account for anomalies observed by astronomers and may change the theory of the Michelson-Morley-Miller experiment.

30. Resonance and quenching of the third principal series line of caesium. C. BOECKNER, *Bureau of Standards, Washington D. C.*—A helium discharge is used as a source for the study of the resonance radiation from the third principal series line of caesium. This is possible, due to the coincidence of a strong helium line with the caesium line. In addition to the resonance line, a number of caesium arc lines are observed. These have their origin in lower levels populated by radiation transfers from the initial $4 P_{1/2}$ level. The effect of helium on the fluorescence radiation is studied. It is found that collisions between helium atoms and caesium atoms in the $4 P_{1/2}$ state transfers the latter only to states differing by less than several hundredths of a volt from the initial state. This type of transfer occurs at approximately every kinetic theory collision. Transfers to states differing by as much as 0.18 volts are improbable.

31. The effect of gases on ionization of caesium by line absorption. F. L. MOHLER AND C. BOECKNER. *Bureau of Standards, Washington*.—Measurements consisted of obtaining sensitivity curves for a space charge tube containing caesium at a constant partial pressure when various foreign gases were put in the tube. Hydrogen and nitrogen at pressures of one or two cm reduce the ionization by line absorption to nearly zero. With helium and argon the effects at the fourth and higher lines approach at high pressure values ranging from 60 to 90 percent of the vacuum value but helium increases the effect of the third line. From data on the effects at different pressures we obtain values for the product of the lives of the excited states of caesium and the effective collision areas. This product remains of the same magnitude for different gases and for different excited states.

32. The spectrum of doubly-ionized antimony. R. J. LANG, *University of Alberta*.—The spectrum of the 49 electron atom of antimony consists of term of even multiplicity of which twenty-six have been found as follows: $(s^2 5p)^2 P$, $(s^2 6p)^2 P$, $(s^2 4f)^2 F$, $(s^2 5f)^2 F$, $(5p^3)^4 S$, $(s 5p^2)^4 P^2 D^2 S^2 P$, $(s^2 5d)^2 D$, $(s^2 6d)^2 D$, $(s^2 6s)^2 S$, $(s^2 7s)^2 S$, $(s^2 8s)^2 S$, $(s^2 5g)^2 G$, $(s^2 6g)^2 G$. The ionization potential corresponding to the approximate value of the deepest term $(s^2 5p)^2 P_1 = 200\ 272$ is 24.72 volts. In Sn II the $(s\ 5p^2)^4 P^2 S$ terms are located and also the $(s\ 5p^2)^2 S$ in In I.

33. Nuclear spin and hyperfine structure. H. E. WHITE, *Physikalisch-Technische Reichsanstalt, Berlin, Germany*.—It appears that when hyperfine structure is to be attributed to nuclear angular momentum or spin i , that the relation $\Delta\nu_f : \Delta\nu_f = m_e : 4im_e$, should approximately

hold where $\Delta\nu_g$ is the gross or multiplet structure separation, $\Delta\nu_f$ the hyperfine structure separation, m_k the mass of nucleus and m_e the mass of electron. From a discussion with Dr. Schüller it appears that the hyperfine structure of $\lambda 5486$ in Li II (Zeits. f. Physik **42**, 487 (1927) $^3S_1-^3P_{0,1,2}$, may be accounted for by assigning an angular momentum $i=\frac{1}{2}$ to the nucleus of Li⁷. From the observed hyperfine structure the $^3S_1(1s2s)$ term and the $^3P_2(1s2p)$ term have normal doublet separations of about 0.60 cm^{-1} , and 0.45 cm^{-1} respectively. From the already known relations in hyperfine structure, the $^1P_1(1s2p)$ term should have an inverted doublet separation of about 0.40 cm^{-1} . The gross-structure difference, $^3P_2-^1P_1$, 5700 cm^{-1} as compared with the hyperfine structure difference $\sim 0.85\text{ cm}^{-1}$ gives a ratio of 6700 in good agreement with the theoretical value 6440. Equally as good agreement between theoretical and observed values is found in several other elements. A more detailed explanation will be given in the Physical Reviews.

34. Average lives of lines of mercury triplet 2^3P-2^3S . R. H. RANDALL AND HAROLD W. WEBB, *Columbia University*.—The average life of each of the three components of the mercury triplet $2^3P_{012}-2^3S_1$, when excited by electron impact under conditions involving negligible ionization has been measured. The method used was that previously described (H. W. Webb, Phys. Rev. **24**, 113 (1924)), in which high frequency voltages are applied in phase to the excitation and detecting systems. From the variation of the current with frequency the rate of decay of the radiation after the exciting impact is calculated. The lines were excited in a sealed-off tube with mercury pressures between 0.004 and 0.03 mm. The exciting voltage was less than ten volts. The excitation was such that there was no appreciable concentration in the excited 2^3P states. A specially designed potassium hydride photoelectric cell was used as the detecting system. Optical filters were used to isolate the line under measurement. The results agree with the assumption that the radiation decays exponentially after impact. For the lines $\lambda 4047$ and $\lambda 4358$ the lives were found to be the same within the experimental error (0.75%), viz. $\tau = 5.75 \times 10^{-8}$ sec. The value for $\lambda 5461$ was four times greater, $\tau = 2.37 \times 10^{-7}$ sec. No satisfactory explanation of these results has been found. It is suggested that the fine structure of the lines may be involved.

35. The comet tail bands of carbon monoxide. LOUIS R. MAXWELL, *Research Fellow, Bartol Research Foundation*.—The experimental arrangement described by the writer (Phys. Rev. **32**, 715 (1928)) for measuring the life in the excited states, can be used for determining whether the emitters of band spectra are positive or negative ions or neutral molecules. This method is now applied to the comet tail bands which were produced by impurities in the tube containing helium when excited by 140 volt electrons. The bands experienced a displacement along their length by such an amount as to show clearly that they are produced by positive ions. This confirms the conclusions which have been made in regard to their origin.—By decreasing the pressure to less than 1×10^{-4} mm these bands appeared strongly without the presence of other bands and with the helium spectrum extremely weak. By circulating helium through the tube at 1×10^{-3} mm both spectra were obtainable while further increase of the helium pressure lessened the intensity of the bands until at 2.8×10^{-3} mm they had practically disappeared leaving only the helium spectrum. This effect is opposite in character to the phenomena found by Merton and Barrett and others where small traces of CO in helium at 20 to 60 mm were capable of producing the comet tail bands quite brilliantly.—Since the positions of the bands are altered by the cross-electric field, it is possible to measure their mean life by the method previously used for the mercury spark spectrum.

36. The application of least squares. W. EDWARDS DEMING, *Bureau of Chemistry and Soils, Washington, D. C.*—By writing general relations between the most probable values of observed quantities and of p parameters, it is possible to get a solution to the general problem. The different relations that may exist between the most probable values and the parameters constitute the distinctions between the various types of problems. The general solution takes the form of symmetrical equations. When $p=0$, it reduces to the so-called "method of correlates." For curve fitting, the general solution can be transformed into two sets of equations;

one gives the parameters, the other corrects the observations. Provision is made for cases where the empirical surface must pass through given points. Heretofore it has been customary to throw all the adjustment on to one group of observations and none on to the others—a practice that often contravenes the foundation of least squares and yields unreasonable results, resulting in unjustified criticism of the principle. The present method allows the proper weight of each observation to be used in the adjustment. The corrections give interesting geometrical generalizations of those discussed by the writer in the Proceedings of the London Physical Society for February 15, 1930.

37. Simultaneous irreversible processes. L. ONSAGER, *Brown University*.—A general theorem applying to simultaneous irreversible processes is derived from the assumption that the dynamical laws are symmetrical with regard to past and future. The derivation involves the consideration of fluctuations. The adaptation to processes obeying linear differential equations of the first (or second) order with regard to the time yields an extension of Lord Rayleigh's "principle of the least dissipation of energy." This result provides a satisfactory basis for certain theorems which were originally derived from the consideration of cycles differing from those accepted in thermodynamics in the essential respect that reversible operation is impossible. One of these theorems applies to thermoelectric phenomena (W. Thomson), another to liquid junction potentials in electrolytes (H. v. Helmholtz), a third one to the Soret effect (E. D. Eastman). A new theorem applying to diffusion is also obtained. An external magnetic field disturbs the straight symmetry in past and future (a rotating frame of reference has the same effect). In such cases another symmetry condition connected with a simultaneous reversal of the time and the magnetic field is applicable. On this basis a relation between the Nernst and the Ettingshausen effects, first proposed by P. W. Bridgman and H. A. Lorentz, is confirmed.

38. Thermodynamics of systems with several equilibria. N. RASHEVSKY, *Westinghouse E. and M. Co., East Pittsburgh*.—Further studies on thermodynamical systems having more than one equilibrium constitution for given external conditions, and discussed in a paper presented at the last February meeting, are made. A reversible reaction between two substances which are either dissolved or gaseous, but which in either case are following not the ideal gas laws, but van der Waals' equation, is considered. It is shown that for certain values of temperature, total volume and other external conditions; the free energy of the system, considered as a function of the ratio of the two reacting substances, has *two* minima. Hence, for given external conditions, the system may have two equilibrium concentrations. In other words, the state of the system is not defined by the external conditions alone, but, as has been shown in a previous paper, it depends also on the previous history of the system. We may say that the system possesses hysteresis. Different possible kinds of such a hysteresis and possible application, especially to some biological problems, are discussed.

39. An acoustical analogy of the Schrödinger wave equation. R. B. LINDSAY, *Yale University*.—Investigation is made of the one-dimensional compressional vibrations of an ideal fluid of variable density (in equilibrium under the action of an external force) confined in an infinite tube of bounded but variable cross section. The non-homogeneity is so chosen that the wave velocity is everywhere the same. It is assumed that the ordinary acoustic equations are applicable except as modified by the non-homogeneity and that the cross section is small enough so that transverse motions may be neglected. It is then found that the problem of determining the allowed vibrations in such a tube satisfying the boundary condition that the condensation $s = \delta\rho/\rho_0$ (where ρ_0 is the equilibrium density at any point and $\delta\rho$ the excess density) shall remain analytic, everywhere < 1 and vanish at infinity, is formally equivalent to the problem of solving a one-dimensional Schrödinger wave equation subject to the usual boundary condition. The appropriate density variation and the shape of the tube are shown to be related to the potential energy of the particle whose motion is described by the Schrödinger equation. As illustrations the free particle, the simple harmonic oscillator and the one dimensional hydrogen atom are investigated. It is believed that generalization to three dimensions will prove possible.

40. A general formulation of the uncertainty principle and its classical interpretation. H. P. ROBERTSON, *Princeton University*.—Denoting the mean value of a quantum mechanical variable α in a state ψ by α_0 and its uncertainty or standard deviation by $\Delta\alpha$, the uncertainty principle $\Delta\alpha \cdot \Delta\beta \geq (h/4\pi) |\gamma_0|$, where $(h/2\pi i)\gamma$ is the commutator $\alpha\beta - \beta\alpha$ of α and β , is obtained for general systems, which may include spin. It is found to be a consequence of the more restrictive inequality $\Delta\alpha \cdot \Delta\beta \geq \{[(\alpha\beta)_0 - \alpha_0\beta_0][(\beta\alpha)_0 - \beta_0\alpha_0]\}^{1/2}$. The former result is interpreted classically as meaning that we can only determine that two quantities $\alpha(p, q)$, $\beta(p, q)$ have values lying between $\alpha_0 \pm \Delta\alpha$, $\beta_0 \pm \Delta\beta$ provided the integral invariant $J = |\Sigma(i) \int p_i dq_i|$ taken over the area normal to these four hypersurfaces in phase space is at least of order h .

41. Thomson effect in zinc crystals. L. A. WARE, *University of Iowa*.—The Thomson coefficient, σ , is directly determined for a group of zinc crystal rods with orientations distributed fairly uniformly over the entire possible range of orientations. At 49.5°C, and at 125°C, the values of σ seem to obey the Voigt-Thomson symmetry relation, although not as good a check is obtained at the higher temperature due probably to increased experimental error. The principal values obtained are: at 49.5°C, $\sigma_{\perp} = 0.98 \times 10^{-6}$, $\sigma_{\parallel} = 0.38 \times 10^{-6}$; at 125°C, $\sigma_{\perp} = 2.09 \times 10^{-6}$, $\sigma_{\parallel} = 1.08 \times 10^{-6}$ Cal./coul./degree C. The increase of σ with increased temperature is greater than has been previously reported for polycrystalline zinc but is in approximate agreement with some earlier determinations by the writer. In addition, specific resistivity and temperature coefficient of resistivity are determined.

42. Thermal expansion of copper-nickel-tin alloy. PETER HIDNERT AND W. T. SWEENEY, *Bureau of Standards*.—In 1926 determinations were made at the Bureau of Standards on the linear thermal expansion of a copper-nickel-tin alloy known as Admiralty nickel or Admic. It is claimed that this white nickel alloy resists corrosion and shows good strength at elevated temperatures. The sample, 1-3/10 inches in diameter, was extruded from 1-3/8 inches and finished hard with a 1/16 inch draught after a suitable anneal. The chemical analysis was as follows: Copper 69.57, nickel 28.70, tin 0.91 percent. Scovill Mfg. Co., Waterbury, Conn. prepared the sample and furnished information about the treatment and the chemical composition. The following coefficients of linear expansion were obtained:

Temperature Range	Average Coefficient of Expansion per Degree Centigrade
20 to 100°C	15.2×10^{-6}
100 to 200	15.5
200 to 300	18.0
20 to 200	15.4
20 to 300	16.3

Data on physical properties of this alloy are given in *Mining and Metallurgy* 8, 474 (1927).

43. A new method for measuring the variation of specific heats of gases with pressure. E. J. WORKMAN, *University of Virginia*.—The method determines the ratio of c_p at a high pressure to c_p for the same gas at a pressure of one atmosphere taken as a standard. The continuous flow principle is used in such a way that the necessity for measuring rates of gas flow and heat input is avoided. A stream of gas at high pressure is brought to a temperature t_1 and passed through a heat interchanger acquiring there a temperature t_2 , after which it is throttled to atmospheric pressure, brought to a temperature t_3 and returned to the heat interchanger, where its temperature again becomes t_2 . If there is no heat leakage the ratio of c_p at high pressure to that at atmospheric pressure is equal to $(t_3 - t_2)/(t_2 - t_1)$. Measurements on commercial oxygen taken at a mean temperature of 26°C and pressures ranging from 15 to 100 atmospheres indicate, when corrected, a pressure coefficient in this ratio 0.0017 ± 0.0001 per atm.

44. The effect of hydrogen ion concentration on the measurement of the mean particle size of emulsions. ISABEL C. WEEKS, *The Pennsylvania State College*. (Introduced by Wheeler P. Davey.)—W. P. Davey proposed (Science 64, 252 (1926)) measuring the mean particle size of emulsions by a water-spreading method. The present work investigates the effect on such measurements of the pH ($=1/\log$ concentration of H^+) of the water used. Three emulsions were tested, stabilized with the sodium soaps of myristic, palmitic and stearic acids respectively. The pH was varied from 3.0 to 11.0 by means of buffer solutions. No effect was found traceable to the buffer materials used. At a pH less than 7.0 (i.e. the water is acid) the area of the water-spread emulsion for a given pressure increases with time without reaching an equilibrium value. At a pH greater than 7.0 (i.e. the water is alkaline) the area for a given pressure finally becomes constant with time, but the values are large and depend upon the pH . In every case the emulsion area was corrected for the area covered by pure buffer. At $pH=7.0$ (i.e. the water is neutral) the water-spread emulsion shows a constant area with time for a given pressure, and reaches equilibrium very quickly. Areas found at $pH=7.0$ are therefore taken as the true areas to be used in plotting pressure-area curves for particle-size calculations.

45. Molecular aggregation. A. M. TAYLOR. *Institute of Applied Optics, Rochester, N. Y.* (Introduced by T. R. Wilkins.)—A brief résumé of the lines of evidence by which molecular aggregation in pure liquids may be recognized; from the surface tension, from viscosity, from optical anisotropy, and from the Raman effect. The question of molecular size in the solid state can at present be answered only by x-ray analysis and by comparison of specific heat data with theory. A third method is suggested based on the Vant-Hoff equilibrium equation $d(\log k)/dt = Q/RT^2$. Q is here the differential heat of solution of the solid in a given solvent, while k is the equilibrium constant regulating the exchange between the molecules in the solid and the molecules in the solution; k may be expressed in terms of the change of solubility with temperature. For iodine the method gives I_2 as the molecular size in the solid state; this agrees with x-ray measurements which show that solid iodine has a molecular lattice of I_2 . Lack of data prevents further application of the method at present.

51. Phenomena in oxide coated filaments. E. F. LOWRY, *Westinghouse E. & M. Co., East Pittsburgh*.—It has been suggested in a previous paper that the phenomena of oxide emission might be explained by assuming that the source of electron emission is a layer of metallic barium occluded on the surface of the core metal. The activity of such a filament is characteristic of this composite surface and the peculiar effects met with are due to the diffusion of the electrons through the pores of the oxide coating. In the present paper experiments are described which tend to support this view. Filaments made by vaporizing metallic barium on clean Konel ribbon give emissions of the same magnitude as those coated with oxide in the usual way but approach saturation rapidly while oxide filaments approach saturation very gradually if at all. The "three halves power" law is obeyed exactly by both types. "Bariated" Konel filaments show very little if any "fading" of emission with time, while considerable fading is experienced with oxide filaments, particularly in a certain range of temperatures and with heavy coatings. No activation of these filaments is necessary other than thermal decomposition of the alkaline earth carbonates in vacuum.

52. Density distribution of electron gas in equilibrium with a hot body. A. T. WATERMAN, *Yale University*.—The variation of potential and of electron concentration with distance from a plane emitting surface is investigated, using Poisson's equation and the equilibrium relation between electron concentration and potential in the form $A = A_0 e^{-V^*/kT}$, where A and A_0 are the Fermi A 's outside and inside the hot surface, respectively, and V is the corresponding potential difference. Solutions are found for the equilibrium condition in the absence of applied field and for negative fields, and assuming the electron gas within the body to be degenerate or classical. Results indicate: (1) that on the average an electron is closer to its neighbors than to the surface, except when very close to the latter, and therefore that the image force explanation of the work function is here not applicable; (2) that space charge is quite competent to give the magnitude of the work function; (3) that if the electron concentration within the body

is that of the atoms, the external gas remains degenerate to approximately 10^{-7} cm from the surface; (4) that an applied negative field of the magnitude required for cold field currents materially alters the electron concentration down into the degenerate region. The current obtainable under retarding fields is discussed with a view to estimating the feasibility of experimental proof of the relations established and of the electron concentration within conductors.

53. A space charge interpretation of thermionic work function. RUSSELL S. BARTLETT, *Yale University*.—We try to account for the thermionic work function by the space charge field of electrons streaming out from the surface and turning back in this same field. To account for the increase in thermionic currents in strong electric fields it is necessary that the work function field extend so far out that an escaping electron is much nearer to its neighbors than to the surface. If we extend Fry's space charge analysis, with classical velocity distribution, right down to the surface of the metal, assuming an electron concentration about midway in the range of prediction, we find something resembling saturation currents, a suitable value for the work function, and an increase of current with strong fields agreeing better with experiment (Proc. Roy. Soc. A121, 456 (1928)) than does Schottky's expression depending on image force alone. A first order correction for Fermi-Dirac distribution brings improvement, though the variation of work function with temperature is too great. But the strict application of the Fermi-Dirac statistics for a degenerate gas, with its large zero point energy, should remove that difficulty, and should provide for an explanation of field currents, since the large fields necessary should penetrate into the region of degeneracy.

54. Effective photoelectric work function reduced by weak accelerating fields. W. B. NOTTINGHAM, *Bartol Research Foundation*.—Photoelectric experiments on thin alkali metal films reported (Phys. Rev. 33, 633 and 1081 (1929)) seemed to indicate a nonlinear relation between current and light intensity and a departure from Einstein's photoelectric equation. A study of amplifier-galvanometer systems for measuring small currents (Journal of Franklin Institute, March 1930), showed that the nonlinearity was in the current measuring system. A thin alkali metal film on nickle or platinum changes the work-function (ϕ) of the surface by a small amount, and greatly alters the space distribution of the electric field against which the electron must work in order to escape. This redistribution makes it possible to reduce the effective work-function (ϕ_e) of the surface by applying a small accelerating field. The photoelectric long wave-length limit is a direct measure of ϕ_e . With a retarding field, ϕ_e is greater than ϕ and the Einstein equation gives the relation between ϕ_e and the potential. At zero field, $\phi_e = \phi$ while with an accelerating field, ϕ_e is less than ϕ . For example, ϕ_e has been observed to be reduced by 1.95 volts by the application of an accelerating potential of 4 volts between the electrodes. A further increase in accelerating potential to 750 volts gave a further decrease in ϕ_e of only 0.32 volt.

55. Photoelectric properties of extremely thin films of alkali metals. HERBERT E. IVES AND H. B. BRIGGS, *Bell Telephone Laboratories*.—Films of alkali metal much thinner than those previously studied (Astrophys. J. 60, 209 (1924)) have been investigated by using an electrometer of approximately 100 times the sensitiveness of the galvanometer used before. Attention has been directed to the variation of emission with the angle of incidence and plane of polarization of the exciting light. In agreement with the earlier work, the ratio of emissions for obliquely incident light polarized with the electric vector in and perpendicular to the plane of incidence decreases as the film is reduced in thickness. The new measurements show further that this ratio continues to decrease with film thickness to the value unity, where no variation of emission with angle occurs, and that with further decreases in film thickness, the relationship reverses, ("normal" greater than "selective") and the emission increases with the angle of incidence of the light. It is suggested that when the alkali metal particles become sparsely distributed their absorption of light corresponds to that of a matt surface (Lambert's law). When the particles are still more widely separated, deviation from Lambert's law occurs and the exciting light is in part that reflected from the underlying platinum surface, stronger for light polarized with the electric vector parallel to the surface.

56. Validity of Einstein's photoelectric equation for red sensitive sodium compounds. A. R. OLFIN, *Bell Telephone Laboratories, Inc.*—Using a photoelectric cell specially designed so that the cathode could be sensitized in a side compartment and then slipped into position within a soot-coated nickel anode, stopping potentials were obtained for electrons liberated by highly resolved light of wave-lengths ranging from 3500Å to 8000Å. The cathode consisted of a nickel plate heavily coated with sodium and specially treated with sulphur and air [abstract 57 Bull. Am. Phys. Soc. 4, 2 (1929)]. The anode of such a cell is not sensitive to light, so the voltage at which the emission from the cathode just becomes zero is a measure of the true stopping potential. Plotting the voltages so obtained versus the exciting light frequencies a perfectly straight line is obtained. From the slope of this line, a value of Planck's constant h equal to 6.541×10^{-27} , significant to three figures, is obtained. It is possible with one cell to obtain stopping potentials for electrons released from sodium before and after treating it with sulphur and air. In such cases the voltage at which the photoelectric emission ceases is the same, but after treatment the current saturates at a higher voltage, exhibiting a change in the contact difference of potential of 0.8 volt.

57. Photoelectric cell thermoregulator. F. G. BRICKWEDDE AND R. B. SCOTT, *Bureau of Standards, Washington, D. C.*—Recently a photoelectric cell was used with a thermocouple as the thermosensitive element to make a new kind of thermo-regulator. There are many laboratory problems requiring automatic regulation to which the photoelectric cell can be applied. Photoelectric cell regulators possess great sensitivity, small lag and a wide range of temperatures over which they can be used and be quickly and conveniently adjusted for operation at any desired temperature. The parts of the thermo-regulator are analyzed and it is shown how they can be modified to adapt this regulator to special problems. Improvements are described and causes of trouble pointed out. A photoelectric regulator has been made which will automatically maintain any temperature from 0° to liquid air temperatures constant to 0.001°. It is operated on a 240 volt D.C. power, without batteries, using only one slide wire rheostat with four sliding contacts to furnish all the sources of potential for the photoelectric cell and its amplifier thus making the regulator less expensive and obviating all the inconveniences of run down batteries.

58. Apparatus for maintaining constant low temperatures. R. B. SCOTT AND F. G. BRICKWEDDE, *Bureau of Standards, Washington, D. C.*—A cryostat of improved design for use in the temperature range from 0°C to liquid air temperatures has been constructed. The cryostat bath is contained in a double-walled cylindrical glass vessel surrounded by liquid air, and the amount of refrigeration controlled by varying the air pressure between the walls. Constant temperature is automatically maintained by the use of a photoelectric cell thermo-regulator operating a heating coil on the stirrer tube. Adequate circulation of the liquid, careful heat insulation, and symmetrical distribution of all the parts assure great uniformity of temperature. The temperature is easily adjusted to the desired value and can be maintained constant to 0.001°C. Nonflammable liquids are used for the bath between 0°C and -150°C.

59. Raman spectra excited by the helium hot-cathode arc and a new type of tube for small volumes of liquid. R. W. WOOD, *Johns Hopkins University*.—A hot-cathode helium arc of great brilliancy, carrying three amperes, kindly supplied by the research laboratory of the General Electric Company of Schenectady, has been very successfully used in combination with a filter of nickel oxide glass for the excitation of Raman spectra. Exposures of less than three hours are required as against fifteen hours with the spiral tube which I described last year. A new type of tube for the investigation of volumes of only eight or ten cubic centimeters of liquid has been developed, adapted to the investigation of liquids of low boiling point or solids which liquify below 100°C.

60. The calculation of the specific heats of solid organic compounds from Raman spectra. DONALD H. ANDREWS AND JOHN C. SOUTHARD, *The Johns Hopkins University*.—It seems to be possible to identify the lines in the Raman spectra of a number of organic molecules with

definite modes of vibration in the molecule (see abstract Number 25). This permits the assigning of the correct number of degrees of freedom to each frequency and it is found that the sum of the degrees of freedom so assigned has a value consistent with the number of atoms in the molecule. If we then consider that the various modes of vibration in the molecule act as independent Einstein oscillators, it is possible to employ the frequencies from the Raman spectra and calculate the specific heat of the molecule for any temperature. This has been done for methyl alcohol, ethyl alcohol, benzene, toluene, chlor benzene and brom benzene over the temperature range of 15° to 260°K. The average deviation between the results so calculated and the experimental values is about five percent.

61. Mosaic crystals of elements. R. H. CANFIELD, *Naval Research Laboratory, Anacostia, D. C.*—Assuming that the atoms of a crystal of an element are all exactly alike and exert mutual central forces, and that the force between any two atoms vanishes for only one value of the distance, it is found that the conditions of stability of equilibrium of the crystal against an infinitesimal generalized strain require that certain series of terms in the second derivatives of the energy function shall be greater than zero. If this is granted, it is shown that any translation of a part of the perfect crystal relative to the remainder causes the potential energy of the lattice to increase. Hence all such imperfections are to be regarded as unstable.

62. Selective maxima in the spectral response curves of light-sensitive compounds as a function of valence. A. R. OLFIN, *Bell Telephone Laboratories, Inc.*—Lindemann proposed a formula for computing the frequency of light under excitation by which a substance should yield electrons most readily. This formula, $\nu = (1/2\pi) [(ne^2)/(mr^3)]^{1/2}$, gives the frequency of an electron revolving in an orbit of radius r about a stationary charge ne [m = mass of electron]. The n term is determined by the valence of the substance, a choice of unity for the monovalent alkali metals corresponding to an electron revolving around a singly charged ion. With the normal valence of the alkali metals, Lindemann computed selective frequencies which have been checked by many observers. Under certain conditions, the alkali metals manifest different valences, such, for instance, as those exhibited in the oxide series Na_2O_2 , Na_2O , Na_3O , Na_4O . These compounds are light sensitive and can be prepared in photoelectric cells. Spectral response curves for such cells exhibit all the selective maxima called for by the Lindemann formula when the value of n is chosen to agree with the valence of the metal. Data are presented showing this condition to be general for the other alkali metals, a maximum response to red or infra-red light being dependent upon the formation of a subvalent compound, as a suboxide.

63. The scattering of atomic hydrogen by gases: mercury, argon, oxygen and iodine. E. G. LUNN AND F. R. BICHOWSKY, *Naval Research Laboratory.*—A beam of hydrogen atoms defined by two small holes passes through a gas-filled space and impinges on a plate coated with molybdenum trioxide. The loss in intensity of the beam due to collision of the hydrogen atoms with molecules of the various gases depends on the sum of the radii of the hydrogen atom and the gas molecules. The collision diameter of the hydrogen atom can then be calculated directly and simply by using the known collision diameters of the several gases. While the collision diameter of hydrogen determined by comparison with mercury is about eight Angströms, that calculated from preliminary results on the scattering in argon and oxygen is about two Angströms. Similar measurements in iodine, made uncertain by a fading of the reduced molybdenum oxide due to oxidation by the atomic iodine formed, indicate a collision diameter of over twenty Angströms. The collision diameter is thus a property of the degree of interaction between the colliding particles. This is in accordance with the Heitler and London picture of chemical reaction.

THE PHYSICAL REVIEW

PLASMOIDAL HIGH-FREQUENCY OSCILLATORY DISCHARGES IN "NON-CONDUCTING" VACUA

By R. W. WOOD

PHYSICAL LABORATORY, JOHNS HOPKINS UNIVERSITY

(Received February 17, 1930)

ABSTRACT

Plasmoidal discharges. A new type of vacuum tube discharge is described, excited by comparatively low voltage high-frequency oscillations (1.7 meters up to 30 meters wave-length) in which remarkable luminous balls, spindles and pear-shaped bodies are formed. These have been reported in earlier papers in *Nature* and the *Phil. Mag.* A study of the conditions under which these bodies are formed and their behavior in magnetic fields has lead to the conclusion that surface charges play a part in their formation. They have been shown to be built of excited molecules, as their spectra are molecular band spectra (O_2 or CO) and since Langmuir has seen in their formation the possibility of plasma oscillations, such as he observed in the mercury arc; they have been named "plasmoids" provisionally.

Red phosphorescence of the glass wall. This occurs in all of the tubes containing oxygen at very low pressure. It appears to be due to low velocity secondary electrons in combination with excited oxygen. Its behavior in magnetic fields has been studied, and it appears when a plasmoid is deflected against the wall by a magnet. The red phosphorescence does not appear until after the high frequency discharge has operated on the glass for some minutes, becoming finally a bright ruby red. The same glass surface phosphoresces green under the impact of high velocity electrons given off from the inner surface of the glass when the external cathode is excited by higher voltages. It may happen that superposed streaks of red and green phosphorescence may occur simultaneously and they can be separated by a magnetic field.

Clean-up effects. Remarkable clean-up effects have been observed, it being possible to have a tube sealed off from the pump which can be made to show either a pure Balmer spectrum of atomic hydrogen (purple discharge) or the green discharge of molecular oxygen. The pressure changes occurring in the sealed off tubes as the type of spectrum changes have been followed with a vibrating quartz fiber manometer.

Spectroscopic investigation. The spectra of the plasmoids, their dark sheaths, and the less luminous gas in which they are imbedded have been investigated by projecting their images on the slit of a spectroscope. The band spectrum of molecular oxygen is seen in the whole tube, but is concentrated in the plasmoids and diluted in their dark sheaths; atomic lines appear as well, the local concentration being different for singly and doubly ionized oxygen.

General nature of discharge. There are two types of discharge, one at very low potentials, suggesting the Townsend discharge (unmodified by space or surface

charges) and a more brilliant one which comes in suddenly as the potential is gradually raised. Plasmoids, however, appear to form with both types, though their shape and distribution in the tube changes as we pass from one type to the other. External electrodes are used in all cases.

IN THE *Philosophical Magazine* for October, 1929, I gave a short account of some phenomena exhibited by very highly exhausted tubes, excited through external electrodes by comparatively low voltages, at a frequency corresponding to a four meter wave. References were made in this paper to earlier work by Kirchner, who first drew attention to the circumstance that, what is usually called a non-conducting vacuum, is excited to bright luminosity by these very high frequencies at comparatively low potentials. During the past autumn I have made a more careful study of these discharges with an oscillator having a wave-length of 1.75 meters built by A. L. Loomis at his laboratory in Tuxedo, New York, and later on in my own laboratory with other oscillators and sources of high potential. The investigation concerned the general nature of the discharges, their behavior in magnetic fields, and the spectra emitted by them, as well as the very remarkable "clean-up" effects shown.

In the earlier paper reference was made to the curious luminous bodies, balls, spindles and pear shaped forms, which usually appeared in the tubes, and it was shown that these luminous masses were formed of singly ionized molecules, either of oxygen, showing the band spectrum, or CO showing the so called "Comet-tail" spectrum, now known to be due to singly ionized CO molecules. Kirchner's original theory to explain the production of a luminous discharge with a potential of only a few hundred volts in a vacuum impervious to the potential of a large induction coil, was that, at these high frequencies, the electrons made "to and fro" excursions ("pendelt") under the rapidly alternating electric force, increasing enormously their chance of ionizing the rarefied gas by collisions.

While I feel convinced that an oscillatory motion of the electron takes place in the discharges, it appears probable that the matter is more complicated than imagined by Kirchner, for the discharges occur equally well when the position of the electrodes and the dimensions of the tube are such as to make these long to and fro excursions impossible.

It seems highly probable that the comparatively heavy ions remain practically at rest, and the circumstance that the luminous bodies are shown by the spectroscope to be built-up of ionized molecules, while the less luminous regions show atomic line spectra, made it appear probable that a careful study of the movements of these bodies under magnetic and electric forces would throw some light on the nature of the discharge.

It is very probable that surface charges on the glass play a large part, for as I showed in an earlier communication, the deflection of the electrons by a magnetic field, as indicated by the movements of the ruby red phosphorescence patches on the inner wall indicated electrons moving away from the electrodes in their vicinity, and towards the electrodes at the opposite

ends of the tube, the electrodes being near the middle. The end of the tube acted as if it had become a secondary cathode. Surface charges are also indicated by the curious circumstance that if the tubes fail to respond to the oscillator, they usually light up immediately if brushed once with a bunsen flame, or even if a lighted match is brought close to them. We thus have a vacuum tube which can be lighted with a match! I have frequently observed the discharge initiated by striking a match at some distance from the tube the effect being due probably to a modification of the surrounding field. In the earlier work sufficient care was not taken to insure a clean inner surface of the tubes, and the presence of CO masked the clean cut effects obtained in the present work.

We will now consider briefly the phenomena exhibited by one of the tubes during the process of exhaustion and subsequently. A tube of soft glass 2 cm in diameter and 30 cm long is blown round at one end, drawn down at the other for sealing, and exhausted with a Holweck molecular pump. The wires from the oscillator are wound once around the tube, forming ring electrodes. The character of the discharge is profoundly modified by very slight changes in the position of the electrodes as will appear presently. The tube was very carefully cleaned with a boiling solution of KOH followed by chromic acid before sealing it to the pump. When the discharge is first started the spectroscope shows a mixture of nitrogen and hydrogen, the former disappearing as soon as the tube is heated, the water-vapor liberated from the glass driving out the nitrogen. At first the color of the discharge is pink, and the spectroscope shows the secondary spectrum of hydrogen as well as the Balmer lines, but after ten or fifteen minutes of operation, the tube being strongly heated from time to time the color changes to the "fiery purple" characteristic of atomic hydrogen.

At this state it may happen, if the electrodes are properly placed, that the discharge shows periodic changes of intensity, along the tube, as shown in Fig. 1a.

The intensity change is not very marked in the case of hydrogen, but, as we shall see presently with only oxygen in the tube, we may have the condition shown in the lower figures, the spindle shaped luminous bodies giving an appearance suggestive of stationary waves. We may heat and pump continuously for an hour or two, no visible change taking place, the color remaining intense purple, and only the Balmer lines showing in the spectroscope. That we have a nearly pure atomic hydrogen (purple discharge) in a tube at very low pressure with well baked walls, is undoubtedly due to the fact that the very high frequency discharge keeps the hydrogen thoroughly dissociated into atoms. A low frequency discharge under these conditions is nearly white, with the secondary spectrum strong, due to the catalyzing action of the walls as shown in an earlier paper. If now the tube is sealed off from the pump and the discharge continued, a most remarkable change occurs in a few seconds. The color changes to pink and the spectroscope or a direct vision prism shows that the oxygen bands in the red-green part of the spec-

trum are developing rapidly and the Balmer lines fading away. In two or three minutes the last trace of hydrogen vanishes, and the color of the discharge is now bright green. It is important to note that the transition from pure hydrogen to pure oxygen occurs only after the tube has been sealed from the pump, which means that a slight rise of pressure is necessary. An explanation of this very remarkable behavior will be given presently. If the tube is joined to the pump by a fine capillary, the oxygen may develop before the sealing off process, for the pressure in the tube will be higher in this case than with a wider connecting tube. The green luminous bodies are now strongly developed and their position and shape alters with every change in the position of the wire ring electrodes, a change in position of one of them of only a millimeter, giving a complete redistribution as shown in Fig. 1, b and c.

Fig. 1. Appearance of plasmoidal discharges under various conditions.

The tube shown in Fig. 1, b-c was flattened at one end and sucked in, producing a dome shaped bottom, like a wine bottle. This was done to see whether the form of the luminous body would be affected by the contour of the inner surface. A flattening of the green spindle was observed, as shown in the figure. An attempt was made to determine the effect of a change of length of the tube, with fixed electrodes by means of a sliding partition, (a short glass tube closed at one end which fitted snugly within the discharge tube) but a discharge formed on each side of it. A tube was then made with a glass partition fused within it, at the center, each half being exhausted separately. With ring electrodes near one end, *both* compartments were excited to equal luminosity, i.e the glass partition served as an electrode quite as well as the wire rings. The excitation of the second compartment was not due to a stray field, as it appeared only when the wire electrodes encircled the other end of the tube.

The glass near the electrodes phosphoresces with a ruby red color, which is very intense, if the tube has been well baked and thoroughly exhausted. If the baking has been less complete the phosphorescence may not appear.

In this case the green discharge is usually brighter, but the spindles and balls are less pronounced.

RED PHOSPHORESCENCE OF GLASS WALL

The red phosphorescence of the glass walls of electrically excited vacuum tubes appears to have been first noticed and studied by Lilienfeld whose papers will be found in the *Verh. der Deutsch. Phys. Ges.* for 1906-1907. It was observed independently by the author some years later in the long tubes used for extending the Balmer series of hydrogen when oxygen was admitted to them. Gehrke and Reichenbeim attributed it also to oxygen, while Lilienfeld considered it due to slow cathode rays, associated with some other undetermined factor, and from certain observations on the magnetic deflection, considered the hypothesis of positive electrons.

In my own study of the subject with tubes excited in a very different manner from that employed by Lilienfeld and, at the time, in ignorance of Lilienfeld's observations, I arrived at first at quite similar conclusions, and frequently remarked that things would be much simpler of explanation if we could admit the existence of positive electrons! Further study however showed that these were not required, and I believe that progress has been made towards the solution of the mysterious red phosphorescence, though there are still points that require further investigation.

In the first place it has been found that high speed electrons, from a single exterior electrode showered with high potential sparks produce a green fluorescence of the glass in tubes containing oxygen at low pressure, the red phosphorescence being produced by electrons of probably lower velocity, when the electrode is attached to one pole of the high frequency oscillator, operating at comparatively low voltage. In this case no green phosphorescence is observed, but in the former case red phosphorescence in general appears in regions of the tube bombarded by secondary cathode rays of presumably lower electron velocity. I feel convinced also that the presence of excited oxygen molecules in contact with the glass walls is also necessary as will appear presently. This may be the unknown factor mentioned by Lilienfeld.

The glass, moreover, must be acted upon by the discharge for some seconds or minutes before the red phosphorescence appears. In one case a streak of green phosphorescence appeared when the discharge was first started, the color changing to red after a few seconds of operation. If the tube was then rotated on its long axis, so as to bring an "untreated" portion of the glass into the electron stream, the green color appeared again, changing presently to red as before.

If a bright discharge is produced at one end of the tube with a single ring electrode until the glass phosphoresces with a red color, and the ring is moved to the other end of the tube, we have no phosphorescence there, although the discharge is of the same character as before. It is evidently associated with a chemical alteration of the glass.

CHARACTER OF DISCHARGE AND "CLEAN-UP" EFFECTS

The duration of the exhaustion, the amount of baking of tube while on the pump, and the operation of the discharge during the pumping, profoundly influence the subsequent behavior of the tube. With a tube of soft glass joined to the pump by a wide capillary (2 mm) the pumping was continued for 3 hours, during which time it was heated with a bunsen flame about twenty times. The discharge was operating most of the time, the color being intense purple (pure atomic hydrogen). When sealed from the pump, the spectrum changed to one of pure oxygen with about ten minutes of operation. After standing over night the discharge, when first started, was again fiery purple, only the Balmer lines showing, which presently faded away and were replaced by oxygen bands and lines, the color changing to green. This process was repeated over and over again, the transition from oxygen to hydrogen, being accomplished in many cases in a minute or two by heating the tube. We thus have a tube with which we can demonstrate either the spectrum of atomic hydrogen or molecular oxygen at will! With continued repetition of the experiment it was found more and more difficult to obtain the hydrogen stage, and the tube finally reached a condition in which only oxygen bands were shown, and the character of the discharge indicated a higher pressure. Heating the tube caused a momentary trace of the hydrogen lines with the oxygen bands but they faded in a few seconds.

I believe that this behavior may be explained as follows. While the tube is on the pump the oxygen and hydrogen formed by the dissociation of water-vapor coming from the glass, are continuously removed allowing fresh water-vapor to come out of the walls. The spectrum is therefore the line spectrum of hydrogen, which always appears with a discharge in water-vapor at low pressures. A few oxygen lines of relatively feeble intensity appear as well.

If now the tube is sealed off from the pump the pressure rises until a point is reached at which no more water-vapor escapes from the glass, and the hydrogen, formed by the discharge is driven into the glass by the discharge, leaving pure oxygen in the tube. This results in a lowering of the pressure, so that more water-vapor can escape from the wall, if the tube is allowed a rest of a day or two, or heated slightly and we again get the hydrogen lines, until all of the freshly formed hydrogen has been driven back into the glass. Repeating the process over and over again gradually raises the pressure of the oxygen in the tube, water-vapor escapes in smaller quantities and it becomes increasingly difficult to get the hydrogen spectrum as has been mentioned. The alternative explanation of the slow return to the hydrogen state would be to assume that it is the hydrogen and not water-vapor that comes out of the glass. If this were so, the gradual rise of pressure with repetition of the experiment would not occur. A different sequence of events was observed in tubes very thoroughly baked out in an electric furnace.

A tube of Pyrex glass, baked during the pumping operation, at a dull red heat for over an hour in an electric furnace behaved quite differently. This tube was not excited electrically during the exhaustion. When first subjected

to the potential of the oscillator there was only a very pale violet discharge, almost invisible. Red phosphorescence of the glass developed in a few minutes and presently a pale green ball (oxygen) appeared between the electrodes. Heating the tube caused the discharge to become brighter, and balls and spindles of green luminosity appeared but the hydrogen spectrum never appeared.

STUDY OF PRESSURE CHANGES IN "SEALED OFF" TUBES WITH QUARTZ FIBER MANOMETER

It was obvious that a careful study of the pressure changes within the tube during these transitions was most important, and a number of tubes were prepared with quartz fiber manometers, (as used by Haber and Langmuir) by which the changes of pressure within the tube as a result of heating, electrical excitation, and repose could be followed.

These manometers are very easy to prepare, no graded seal being necessary. We have only to draw a fiber 8 or 10 cm long by hand (diameter about that of a very fine hair) drop it into the tube which has a round bottom like a test tube, heat the bottom to the fusing point and then quickly invert the tube, holding it vertical. The fiber will swing to the axis of the tube and remain firmly fixed to the glass. If it is off center, hold the tube horizontally and gently heat the glass at the point of attachment with a small flame until the fiber has sagged to the proper position. The fiber is illuminated by a lamp placed at the side and viewed through a low power microscope with micrometer eye-piece. By gently tapping the tube the fiber is thrown into vibration, and the time for the decrement to half amplitude taken with a stop-watch.

With a tube of soft soda-glass sealed off from the pump, after a one-hour pumping with the discharge operating continuously and repeated heatings (up to the appearance of the *D* lines of sodium) the color was fiery purple and the spectrum that of atomic hydrogen. This indicates water vapor at low pressure in the tube. The vibrating quartz fiber sank to a half amplitude value in 12 seconds. When on the pump the time for half amplitude decrement was 30 seconds. This showed that the pressure had risen after, or during the sealing off process.

The tube was now subjected to the high frequency discharge until the hydrogen spectrum was replaced by that of pure oxygen. The time for half amplitude decrement, which in future we will call H.A.D. was now found to be 30 secs, the same value as when on the pump. After operating for half an hour the time for H.A.D. had decreased to 15 seconds; showing that the oxygen pressure was increasing. The tube was now gently heated with a flame. Purple discharge of hydrogen and time of H.A.D. 7 seconds. Ran discharge until only pure oxygen spectrum. Time of H.A.D. 15 seconds, as before heating.

The inference from these observations is that, under the conditions of these particular experiments in which prolonged heat treatment was not

given to the tube, water-vapor, liberated by heating the tube is completely "cleaned-up" by the discharge, while oxygen formed by the action of the discharge upon the glass or upon water vapor contained within the glass does not "clean-up" but accumulates in the tube with continued operation. This is not the case with a tube subjected to long heat treatment.

With a Pyrex tube the following results were obtained. At the start the spectrum showed both hydrogen lines and oxygen bands. Time of H.A.D. 25 seconds. Heated until discharge white (Balmer lines and band spectra of hydrogen). Time of H.A.D. 4 seconds. We now have a relatively high pressure of water-vapor in the tube. Operating for 1 minute, time of H.A.D. 15 seconds. Operating for 5 minutes, time of H.A.D. 25 seconds. Oxygen spectra only. This indicates that *most* of the oxygen and all of the hydrogen of the original water-vapor present is driven into the glass by the discharge.

With a Pyrex tube baked in a furnace at a dull red heat, with the Holweck pump operating, for over an hour, the time of H.A.D. of the fiber was four minutes and 30 seconds! Discharge at first pale violet, with faint pink fluorescence of the glass. Red fluorescence developed in five minutes with faint green glow of oxygen in the tube. The time of H.A.D. was now 45 seconds. The elimination of water-vapor was evidently fairly complete in this case. Three days later the time of H.A.D. before starting the discharge, was found to have increased to 65 seconds. With the discharge operating the time was 90 seconds, and after running for half an hour it was back to 65 seconds. After 2 1/2 hours of operation by the discharge the time increased to 5 min. 40 secs., indicating a pressure as low as, or lower than when the tube came off the pump. After the lapse of several weeks, the oxygen discharge was strong (green plasmoids) and the time of H.A.D. was eight seconds, which changed to 45 seconds after a one minute operation on the five meter oscillator.

These results show that in a well-baked out tube the oxygen "cleans-up" but that it appears again after the tube has stood for some time, or been subjected to heat. The liberation of oxygen by heat and its rapid "clean-up" by the discharge can be repeated over and over again. Nitrogen and neon, introduced into the tube were rapidly cleaned-up.

GENERAL NATURE OF THE DISCHARGE

Langmuir, from his study of the oscillations which occur spontaneously in a mercury vacuum arc excited by a low voltage direct current, developed a theory based on the hypothesis that a cloud of ions served as a medium in which electrons could oscillate to and fro with a frequency dependent on the density of the ions (i.e. the number in unit volume). A region filled in this way with ions and electrons he called a "plasma," and he suggested to me that very probably the phenomena shown by my tubes were closely related to those which he had observed with the mercury arc. The circumstance that the spectroscopist shows that the luminous balls, spindles and pear shaped bodies are made up of singly ionized molecules, identifies them with Lang-

muir's plasma, (at least this is a plausible hypothesis to make), and on this account I propose, for the present at least, to call them *plasmoids*.

Before taking up in detail the subject of the type of discharge in which the plasmoids are formed, it will be well to consider some effects observed in the same tubes when operated by high potentials of lower frequency, as with hammer interrupter, or intermittent in which the character of the discharge is quite different. Some of the phenomena manifested can be considered to advantage in any effort to formulate a theory of the "plasmoidal" discharges.

DISCHARGE BY "LEAK-TESTER"

This apparatus, sold for therapeutic purposes, and used in physical laboratories for hunting for leaks in vacuum systems, generates a rapidly alternating intermittent potential sufficient to produce a shower of sparks an inch or more in length from its single terminal to any earthed conductor. Excitation of the highly exhausted tubes by this apparatus results in phenomena quite different from those observed with the high-frequency sets.

If the single electrode is applied to the under wall of the tube near one end a patch of green fluorescence is observed above it, and two strips of red

Fig. 2. Red and green phosphorescence patches. Low frequency excitation.

phosphorescence appear along the sides of the tube half way between the electrode and the green patch as shown in Fig. 2. Figs. 2, 3, 5, 7, 12, 13 and 14 are reproduced as "negative" i.e. bright parts of the discharge are black.

If the finger is touched to the upper wall at the opposite end of the tube, a patch of red phosphorescence appears below it on opposite wall. If the thumb is then applied to the wall over the red patch, two red streaks appear on the sides of the tube, half way between the thumb and finger, and if a third finger is applied over one of these it disappears at once and the remaining red streak in the opposite side becomes much brighter. These effects indicate that the red phosphorescence is caused by a discharge of some type, which initially filled the tube uniformly, but which is driven away from those parts of the wall which are "grounded" by an exterior electrode (the finger) and forced against the opposite wall. The depressed "discharge" appears as a faint green glow.

As a substitute for the two fingers and the thumb I wound a "grounded" strip of aluminum around three quarters of the circumference of the tube. The bright red streak appeared along the center of the gap and extended along the wall down the tube towards the electrode. Fig. 3, a.

If a wire, *W* held between the fingers, was brought up towards the red streak from below, the streak was deflected upwards spiraling around to the back of the tube Fig. 3b, while it was deflected downwards if the wire point was brought down from above. If the wire was touched to the outer wall exactly over the center of the red streak, it "forked" into a *Y*, the two branches curving around the wall and uniting at the back. Fig. 3c, very much as would a thin jet of water squirted along the inner wall, and divided into two jets by a small obstacle. The wire had little or no effect if brought up to the red streak in the region of the gap in the aluminum cylinder.

The red streak was also deflected by a magnetic field, upwards or downwards according to the direction of the field. Care was taken to ensure that this deflection was due to the field and not to the mere approach of the metallic mass. The direction of the deflection indicated electrons moving along the inner wall from left to right, i. e. *towards* the electrode.

The deflection by the magnetic field occurred only for that portion of the red streak beyond (to the right of the cylinder). The portion lying between the opposed edges of the $3/4$ cylinder appeared to be held firmly fixed in posi-

Fig. 3. Deflection of red streak of phosphorescence by grounded wire.

tion by electric forces, while the portion outside was free to move under the influence of the force applied by the magnetic field.

It is worthy of comment, in connection with the forking of the streak into a *Y*, when the point of a wire is placed over it, that the repulsive force due to the wire apparently exerts no influence on the electron (?) stream producing the red phosphorescence streak until it reaches the point immediately under the wire, and that the stream is not driven away from the glass wall towards the axis but merely divided laterally into two streams, which spiral around the tube wall in opposite directions, meeting on the opposite side.

The stream thus appears to have a tendency to stick to the wall, once it has been brought into contact with it by the electric forces set up by the grounded cylinder of aluminum.

In another tube in which the pressure was higher (?) the red streak was bent into an arc by the approach of the wire, i.e., the deflection occurred only in the neighborhood of the wire, as shown in Fig. 3, d. It seems possible that, in this case electron streams from opposite ends of the tube were uniting at the point near the wire. In this case the streak extended nearly down to the

leak-tester and was more sensitive to the approach of an earthed conductor. It was also possible to drive it off the wall entirely, by the approach of an earthed conductor directly above it. A very important observation was made with another tube fitted with the three quarter cylinder of aluminum, and excited at the other end with the leak tester.

The streak of phosphorescence of yellowish color extending out from the gap in the cylinder towards the electrode, appeared to be a mixture of both types, green and red superposed, the latter more easily deflected by the wire or magnet. As the wire was brought up, the red streak was pushed aside, leaving a green streak almost undisturbed, and the same thing could be accomplished with a magnet. When the two streaks were thus separated the original yellow color vanished, being decomposed into its constituents pure red and green. This seems to indicate that we have high velocity electrons giving the green streak, and low velocity electrons, in conjunction with oxygen, giving the red streak. The green streak was visible only in the immediate vicinity of the aluminum cylinder, while the red one extended down the tube nearly to the electrode. If the wire were approached to the tube immediately above the red streak near its end (i.e., at a considerable distance from the gap in the cylinder) it could be made to disappear from the wall and reappear on the opposite wall, the electron stream having been pushed across the axis of the tube. If however the wire was brought up at a point nearer the cylinder the deflected electron stream clung to the wall, curving around the inner wall as a spiral, as has been shown previously (Fig. 2, b).

EXCITATION BY 30 METER OSCILLATOR

The excitation in this case was brought about by simply holding the tube partly within the large coil of copper ribband carrying the oscillatory current. Two large green plasmoids were formed, one at each end, with sharply defined rounded ends facing the ends of the tube and fading away gradually towards the center which were repelled by bringing up the finger to the wall. The tube contained only oxygen at fairly low pressure, but there was no red phosphorescence. On pushing the tube entirely within the coil the discharge vanished, showing that it had been excited by the electric field outside of the coil and not by electro-magnetic induction.

The same tube excited by the "leak-tester" showed only green phosphorescence of the glass with no trace of red. The tube was then excited by the two meter oscillator, and red phosphorescence developed in two or three minutes, accompanied by formation of green plasmoids. This result was due to a partial clean-up of the oxygen i.e., the vacuum was improved.

On exciting again with the leak-tester a red phosphorescence mixed with green in an irregular manner was obtained.

Introduced once more into the coil of the 30 meter oscillator, the projecting end being held with two fingers and the thumb, a single plasmoid formed, tapering to a point on the side towards the finger, and rounded on the end towards the coil. A streak of red phosphorescence formed on the

glass extending from the region between, but not covered by the fingers, to a point opposite the tapered end of the plasmoid. If now the end of a wire held in the fingers was brought up to the wall on the side opposite to that on which the red streak had formed, and near the pointed end of the plasmoid, the latter turned up and joined the red streak, i.e., it was repelled by the wire.

It seemed probable to me that the red streak produced by grasping the tube with the fingers was produced in each case at those moments at which the opposite end of the tube was anode. In the case of the excitation by the leak-tester it will be remembered that red phosphorescence streaks were produced at each end of the tube Fig. 2, a and Fig. 3, a.

If the above hypothesis is correct, the red streaks should not appear simultaneously but in alternation. Examination of an ordinary Geissler tube excited by the leak tester in a waggled mirror showed that its polarity alternated in unison with the vibrations of its small "hammer-break," but the light of the red streaks was not bright enough for a conclusive test in this way, the single images seen in the mirror being rather feeble. A stroboscopic method was therefore adopted, by which the tube could be observed at rest and continuously.

STROBOSCOPIC EXAMINATION OF DISCHARGE

The tube was excited by connecting a single ring of wire, wound around one end of the tube with one pole of a 20,000 volt (60 cycle) transformer. The other end was furnished with an earthed three-quarter cylinder of aluminum foil, as before.

Red phosphorescence appeared close to the ring, and as a red streak in the gap of the cylinder. The tube was viewed through a slot in a card-board disk mounted on the shaft of a synchronous motor operated on the same 60 cycle circuit as the transformer. Only one red patch could be seen at a time, the one visible depending upon the position of the eye as it was moved around the circumference of the disk. This experiment appears to prove that in all of the experiments, in which, with a single electrode at one end of the tube, we have electrons moving from the other end towards the electrode, the motion occurs only at the moments at which the electrode is anode. This applies also I believe to the high frequency experiments, in which plasmoids are formed, and should be taken into account in framing a theory of the formation of the plasmoids. Experiments were also made to ascertain how low a frequency would produce a visible discharge.

If the tube were placed between the poles of a small Holtz machine, no luminosity whatever appeared within the tube, though the potential was high enough to cause sparks to jump around the wall. This same tube, on the five meter oscillator with a potential sufficient to give a spark of only half a millimeter or less, showed a brilliant green plasmodial discharge. A small rotating commutator was now made by pasting tin-foil strips along the edge of a disk of ebonite mounted on the shaft of a small motor. By means of this the steady potential of the Holtz machine could

be converted into an alternating potential. Luminosity appeared within the tube with alternations as low as six per second and reached a maximum at about fifty per second. The discharge vanished as the speed of the commutator increased, for reasons which are not quite clear. Possibly the conductivity became so good that the machine could not build up potential.

THE PLASMOIDS

The study of the plasmoids has been conducted along two quite different lines. (a) Their formation and the changes which they undergo when the form and position of the external electrodes are altered, and their behavior in magnetic fields have been very carefully investigated, with oscillators of different frequencies and with the gas at different pressures. (b) Spectroscopic data have been obtained in regard to the radiations emitted by the plasmoid, by its relatively dark sheath and by the more or less uniformly luminous gas in which it is embedded. It seemed probable that a determination of the distribution in space of singly and doubly ionized atoms and the singly ionized molecules, would be of help in ascertaining the physical processes involved in the plasmoid formation.

There appear to be two distinct types of discharge, one in which the luminosity of the gas is low and the other in which it is high. Plasmoids are formed in both cases, but the transition from one type to the other is abrupt.

This suggests perhaps a transition from a "Townsend discharge," to a glow discharge, space charges and charges on the wall being absent in the former, and the potential drop merely the normal drop from anode to cathode while the "glow discharge" results when ionization becomes more pronounced, and space charges are present.

The transition from one type to the other was well shown in the case of a very highly exhausted tube containing oxygen as the residual gas. It was furnished with two ring electrodes formed of single turns of fine wire wound tightly around the tube.

With the lowest potential capable of exciting a luminous discharge, a pale green disk shaped like a double convex lens appeared midway between the ring electrodes as shown in Fig. 4, a. As the potential increased the disk expanded to the form shown in Fig. 4, b, while a further increase of potential caused the sudden appearance in its place of a much brighter green plasmoid in the form of a prolate spheroid, Fig. 4, c. My first attempt to explain the formation of the plasmoids with their sharply defined smooth surfaces, was along the lines usually followed in accounting for the stratifications in gas discharges, namely that the plasmoid surface represented an ionization caused by electrons which had acquired the requisite velocity after leaving the cathode. This works out well for cases a and b of Fig. 4, for the equipotential surfaces of the ring electrodes are about as shown in Fig. 5 which is a cross section through the rings. At low potentials (as in Fig. 4, a) ionization does not result until the electrons have reached equipotential surfaces 1, and the lenticular luminosity appears in the region between them. At a slightly higher potential the electrons have acquired the requisite velocity

when surface 2 is reached, and the region between these surfaces is luminous as in Fig. 4, b. The sudden production of the spheroidal plasmod at a slightly higher potential may result in part from the formation of negative

Fig. 4. Change in shape of the plasmod with increasing potential.

charges on the tube wall between the electrodes, but the complete explanation in this case probably requires the introduction of other factors, such for example as the plasma oscillations imagined by Langmuir.

It appears possible that if we could apply a stroboscopic method to these very high frequency discharges we might find that the brilliancy at opposite

Fig. 5. Equipotential surfaces of ring electrodes.

ends of the plasmod oscillated in unison with the discharge, i. e. the rounded ends facing the ring electrodes became luminous in alternation. My reason for considering this possible was the circumstance that in the case of a short tube excited by introduction into the helix of the thirty meter oscillator two plasmods were formed as shown by Fig. 6. That these occur in alternation

Fig. 6. Plasmods formed with 30 meter oscillator.

and not simultaneously is indicated by the behavior of the discharge at low frequency as examined with the stroboscope. If now the conditions were such as to bring these plasmods closer together we should have the single

spheroidal plasmoid referred to above. The tube in which the lenticular and spheroidal plasmoids formed was excited with the 1.75 meter oscillator by means of two disk electrodes applied on opposite sides of the tube as shown in Fig. 7.

These give a field of simple type, which is easy to calculate, with a potential sufficient to give a spark about half a millimeter long. With a potential giving a spark perhaps half a millimeter in length a brilliant green plasmoid shaped like a double convex lens appeared midway between the electrodes and parallel to them. Fig. 7, a. The plasmoid was surrounded by a dark sheath and two dark arches covered the electrodes as shown in the figure. As the potential was lowered by reducing the filament current, the lenticular disk contracted, remaining very bright however, but suddenly was replaced

Fig. 7. Change in shape of plasmoids with decreasing potential and magnetic deflection of plasmoid (c).

by a sphere of low luminosity surrounded by a wide dark sheath. Fig. 7, b. If the pole of a small bar magnet was brought up to the wall, in the condition "a" the plasmoid was squeezed to one side and deflected upwards as shown in Fig. 7, c. The magnetic field was such as to deflect downward moving electrons to the left and upward moving ones to the right. The formation of the sphere and disk I am unable to explain.

The development of plasmoids at periodic intervals along the tube, as shown in Fig. 1, I was at first inclined to ascribe to a zig-zag reflection of the electrons from surface charges built up on the inner walls by electron impact. It seemed, however, highly improbable that such sharp localization could be produced in this way, or that a movement of one ring electrode through a distance of only one or two millimeters could cause such a change in the paths of electrons down the tube as to cause a complete redistribu-

tion of the plasmoids in space. Langmuir's theory that the plasmoids are oscillators having a definite frequency of vibration seems to be a much more promising line of attack.

Nevertheless, certain observations have been made which apparently show that a reflection in the manner imagined actually takes place. In a tube at very low pressure, containing only oxygen and excited by a single disk electrode placed close to the outer wall, the following phenomena were observed as the capacity of the condenser in the oscillatory circuit was increased from zero. It must be remembered that with the variable capacity set at zero, the circuit is practically interrupted and the potential is very low if oscillations are present at all. As the capacity is increased a patch of ruby red phosphorescence appears on the upper wall of the tube immediately over the disk, with an area considerably larger than that of the disk, and a second red patch on the lower wall of the same diameter as the disk, as shown in Fig. 8, a.

Fig. 8. Reflection of slow electrons by surface charge.

The only way in which I can account for the circumstance that the lower red patch exactly covers the region immediately above the disk electrode is to assume that some of the electrons moving along the lines of force, when the disk is negative fail to reach the upper surface before the field reverses and hence travel backwards along the reversed lines of force to their starting point.

The paths of the electrons through the gas is marked by a faint green luminosity. If the capacity is made slightly greater, which increases the potential, the upper red patch divides at the middle and spreads out, the glass ceasing to phosphoresce immediately above the electrode, and two new red patches appear in the lower wall as shown in Fig. 8, b.

The cause of the division of the electron stream over the electrode results perhaps from the formation of a negative surface charge immediately above the electrode, while the two lower red patches of phosphorescence, appear to be due to the downward deflection of the oblique streams of electrons by negative surface charges at the upper red spots. A slight further increment of capacity results in the sudden birth of two plasmoids to the

right and left of the descending streams. The reversal of the electron stream alluded to above was also indicated in a vertical tube so highly exhausted that practically nothing but red phosphorescence was observed, (with a disk-electrode at the bottom). In the upper two thirds of the tube and at the bottom upward moving electrons were found, while a strong downward stream was indicated by the magnetic concentration of red phosphorescence about one third of the way up. This stream appeared to me to be due to the pulling back of the tail end of the upward electronic blast, when the disk became anode. This case will be alluded to again presently.

If the oxygen is at a slightly higher pressure and we gradually increase the capacity in the oscillating circuit, we get a quite different sequence of events, and can watch the birth of a plasmoid. With a moderate capacity the discharge has the appearance indicated by Fig. 9, a.

Its color is yellow-green of much greater intensity than in the previous case and there is a dark arch over the electrode. The upper wall shows a feeble red phosphorescence, indicating that some of the electrons succeed in reaching it. There are also indications of a segmentation at *A*, which is

Fig. 9. Birth of a plasmoid.

destined to become the breaking point of the discharge when the plasmoid forms. If now a magnet pole is brought up from the side (of polarity such as would cause upward moving electrons to be deflected to the left) the portion *A* is squeezed to the left and a large and perfectly formed plasmoid develops Fig. 9, b and c.

With an oscillator of five meters wave-length, and a single disk electrode applied to the flat end of the tube the plasmoid development as the capacity of the condenser was increased is illustrated in Fig. 10.

The total capacity of the condenser was about 300 cm and the scale was graduated to equal divisions from 0 to 100. The capacity of the condenser is given below each figure. With the two smallest capacities, the discharge is of the first type and of a very feeble green color, the plasmoid having the shape of a spear-head.

Increasing the capacity to 11 causes a sudden increase in luminosity and two plasmoids form of the shape indicated. With capacity 16 the upper rounded end of the large plasmoid streams up to a point, and at capacity 20 a break to the brighter type of discharge occurs and two sharply defined plasmoids appear at opposite ends of the tube. Two rings of red phosphorescence

appear immediately above and below the lower plasmoid, due probably to reflection of the electrons from charges on the tube wall, or possibly to the upward electron stream from the disk cathode and the downward stream which occurs when the disk becomes anode, a condition mentioned a moment ago. If a magnet pole is brought up to the lower plasmoid, both plasmoids contract and disappear at the same moment, but if the magnet is brought up to the upper one it contracts and vanishes but the lower one remains unaffected.

I think it highly probable, in view of the stroboscopic experiments previously described, that the two plasmoids appear in alternation as the field reverses, the upper plasmoid appearing as a result of a negative charge on

Fig. 10. Plasmoid formation with increasing potential.

the wall of the tube above it, at the moment when the electrode becomes anode. The application of the field at the lower end prevents the electrons, in part at least, from reaching the upper end of the tube, and this probably is responsible for the contraction and disappearance of the upper plasmoid.

The effects of a magnetic field on the plasmoidal discharge is very complicated, due, probably to the circumstance that we have electron streams moving in opposite directions but with different velocities at the same point in the tube. These streams do not of course occur at the same instant but in alternation as the polarity of the oscillator reverses, and they will be deflected in opposite directions by the field. This two-fold deflection is often observed at the center of the tube.

The magnetic field, in some cases, causes the plasmoids to shrink and disappear, in others it causes the birth of plasmoids where none existed previously. It has been found extremely difficult to systematize the multitude of different effects observed, or draw any very definite conclusions from them, and only a few selected examples will be given. The others will be kept on record, as they will be of value in testing any theory of plasmoid formation that may be developed subsequently. It will be best to begin with what appears to be the simplest case, a tube containing oxygen at such low pressure that scarcely any trace of plasmoid occurs. The pale green discharge filling the tube quite uniformly, when excited by a single disk electrode at the base and the five meter oscillator. A small U-shaped magnet was used, much larger than shown in the figure in such a position that the lines of force were perpendicular to the paper in Fig. 11. The intens-

Fig. 11. Magnetic deflection of discharge.

ity of the luminosity fell off gradually towards the top of the tube where it was practically zero. The top of the tube showed a faint red phosphorescence, which was deflected to one side when the magnet was 20 cm from the tube, the direction of the deflection indicating upward moving electrons. On moving the magnet down the tube it was necessary to bring it up closer to cause red phosphorescence on the wall. This indicated that the upward moving electrons had a higher velocity half way down the tube than at the top, due perhaps to a reversal of the field direction during their flight from the disk cathode towards the top of the tube. A small plasmoid formed along the axis of the tube in this stage Fig. 11, b. On bringing the magnet closer to the tube a bright red patch formed on the opposite wall below the magnet, indicating electrons moving down, the plasmoid disappeared and the luminous discharge was pressed against the wall terminating at the spot of red phosphorescence. Fig. 12, c. The inference appears to be that we have at

this point, electrons moving down with a velocity a little greater than that of the electrons moving up, the streams occurring in alternation of course.

On moving the magnet down the tube, two red patches formed on the right hand wall, and one on the left half way between them, Fig. 11, d, and the discharge appeared to zig-zag across the tube as shown. This case is more complicated, and I cannot account for it by considering simply two electron streams moving in alternation in opposite directions with different velocities.

Appearances suggest the formation of surface charges and reflection of the electron streams as in a former case (Fig. 8, b.). Some of the effects described above might be explained by assuming upward moving electrons along the inner wall, the downward stream being at the center, but this seems improbable. We will next consider the case of a tube with oxygen and CO at low pressure in which a white plasmoid formed at the top of the tube with its head pointing downwards as shown in Fig. 12, a.

If the pole of the bar magnet was brought up from behind towards the tail of the plasmoid, it disappeared when viewed from the front but was still visible when viewed from the side, due to its having been spread out

Fig. 12. Magnetic deflection of plasmoid.

into a fan. This would indicate electrons moving both up and down. No phosphorescence of the glass was observed. On bringing the magnet closer a new sharply defined tail formed, and the head of the plasmoid was pulled up; at the same time the tail bent to the right, finally touching the glass forming a patch of red phosphorescence on a closer approach of the magnet. Downward moving electrons were indicated in this case.

With the magnet still closer to the tube a faint red patch appeared on the left hand wall, below the magnet, due to upward moving electrons.

If the magnet was approached immediately below the plasmoid, or even below the bulbous expansion of the tube, the plasmoid contracted and vanished, without suffering displacement.

When the magnet was brought up to the plasmoid shown in Fig. 10, Cap. 11, the upper end was deflected to the right and the lower end to the left red spots forming on the wall, indicating electrons streaming out from the center of the plasmoid through its upper and lower surface. In this case the discharge was of the first type (Townsend?).

In other cases the magnet indicated electron streams flowing into the opposite ends of the plasmoid. Elongated plasmoids were constricted or broken into two, by the magnetic field the broken ends being deflected in

opposite directions against the wall forming red spots, the indication in this case being electron streams flowing out of the broken ends.

It has not been found possible to systematize these observations, doubtless due to the fact that the field, by deflecting electrons, establishes a new condition in the tube (destruction or rupture of a plasmoid and a redistribution of surface charges) and the effects we observe are those produced by the field on this modified discharge. In general I have found that whenever a plasmoid is pushed against the wall by a magnet red phosphorescence is produced.

In the condition shown in Fig. 10, Cap. 20, if the magnet pole is brought up from behind the upper plasmoid, the plasmoid slowly collapses to a point and disappears, red phosphorescence appearing on the left hand wall indicating electrons moving down. The oxygen pressure was higher in this case than in one previously mentioned, in which an upward electron stream was found in the upper two thirds of the tube.

SPECTROSCOPIC STUDY OF PLASMOIDAL DISCHARGE

In this study an image of the discharge was focussed on the spectrograph slit, so that a point-to-point correspondence obtained. It was found that the spectrum of the faintly luminous discharge in which the plasmoids were immersed, (with pure oxygen only in the tube) showed the bands of the

Fig. 13. Distribution of intensity in spectrum lines and bands.

oxygen molecule, and the atomic lines due to OII and OI. The discharge in the single case which we shall consider was produced with the 1.7 meter oscillator with two wire ring electrodes, the plasmoids having the form shown in Fig. 13. The slit covering the portion shown by the dotted line. In this diagram the local intensity of a line is roughly indicated by its width. The atomic line due to OI was of uniform intensity throughout its length, the OII lines showed a slightly greater intensity in the vicinity of the plasmoids, two lines (oxygen triplets) between the green and blue bands were of uniform intensity except at the bottom of the tube, where they were very faint, while the bands due to oxygen molecules were much more intense in the plasmoids, the intensity decreasing abruptly at the plasmoid surface. This shows that in the plasmoid we have a concentration of excited oxygen molecules, while the concentration in its dark sheath is less than in the luminous discharge in which it is embedded.

IONIZATION OF HELIUM BY POTASSIUM POSITIVE IONS

BY RICHARD M. SUTTON AND J. CARLISLE MOUZON
CALIFORNIA INSTITUTE OF TECHNOLOGY, PASADENA

(Received February 18, 1930)

ABSTRACT

A continuation of previous attempts to ionize gases by positive ions has been extended to helium using potassium positive ions as high as 750 volts accelerating potential. At pressures between 0.01 and 0.1 mm there is definite evidence of ionization of helium above 150 or 200 volts accelerating potential. The effect is much smaller than in the gases previously reported, but it may be distinguished from the secondary emission of electrons from the metal parts under action of the positive ions. Great difficulty was encountered in changes of intensity of ionization due to impurities in the helium. Some of the uncertainties in previous work have been removed by changing the relative positions of electrodes.

IN A previous paper by one of us¹ evidence was offered for the ionization of argon and neon by potassium positive ions. It was determined that these positive ions could produce ionization which was distinguishable from other effects produced upon the metals in the tube when the accelerating potential was in excess of 150 volts. An inherited error in calibration of the McLeod gauge used for pressure measurement caused a misstatement in that paper regarding the pressure range over which the effect of ionization is found. The pressure range is nearer 0.005 to 0.1 mm which partially obviates the argument concerning unusually long mean free paths of the positive ions. The indication is that their paths are comparable with, but slightly longer than, the mean free path calculated from kinetic theory data.

This work has been extended to the study of helium in a new tube using electrical connections practically the same as previously described. Fig. 1 shows the tube with its electrical connections. The chief features in which it differs from the previous tube are (1) a ground glass joint by which filament changes may be more easily effected, (2) greater space between collector *S* and grid *G* from which the products of ionization are collected, (3) a flat plate *P* placed only 2 mm above the grid *G* and parallel to it. The ground glass joint is made in two parts, the upper part being coated with graphite, the lower portion coated with stopcock grease and sealed with mercury. A vacuum connection between these two parts minimizes the danger of stopcock grease entering the tube. The filament and cathode leads are mounted in this joint so that the filament may be easily removed and recoated with Kunsman catalyst. The cathode is, as before, a steel cylinder completely enclosing the filament; however, the channel through which the positive ions emerge into the upper part of the tube has been made smaller (1.5 mm diameter) and the hole in the collector through which it projects has been

¹ R. M. Sutton, Phys. Rev. 33, 364 (1929).

made smaller (3 mm diameter) so that the field between collector and grid is more uniform. By placing the grid 2.5 cm above the collector *S*, a larger region is available from which to collect the products of ionization. Furthermore, the region above the grid is greatly reduced from the previous case so that the amount of ionization produced between the grid and upper plate has a negligible effect upon the plate current (I_p) of positive ions. It was found that the reflection of positive ions from the plate was extremely small or negligible so that the V-shaped plate previously used to reduce reflection was eliminated.

The helium used was obtained in moderately pure form from the United States Bureau of Mines at Amarillo, Texas. It was further purified by passing over oxidized copper turnings and charcoal in liquid air until it was spectroscopically pure. As an additional precaution, the helium was passed through

Fig. 1. Experimental tube and connections.

a magnesium discharge tube before its introduction into the experimental tube. The ionization properties of the gas seem to be particularly sensitive to impurities, increasing very materially with amounts of impurity which must be only a few percent of the total gas pressure. It is desired to study this aspect of the ionization more carefully in the future under controlled conditions. Until now, however, the effort has been to work with the purest gas obtainable. Consequently, whenever the gas gave indication of contamination by reason of marked increase of ionization without measurable change of pressure, it was rejected and fresh gas was admitted to the apparatus. This increase may be due in part to ionization of impurities by collision with helium excited by positive ion bombardment.²

The system of measurement consisted in directing the potassium positives through the narrow channel in the cathode into the region between the col-

² G. P. Harnwell, *Phys. Rev.* **29**, 683 (1927).

lector S and plate P . The potential of S was maintained 20 volts positive with respect to the cathode (ground) thus preventing positive ions from reaching the collector directly. Any electrons liberated from the grid or from the cathode under impact of the positive ions would reach S in case they had such initial direction as to enter the field of this collecting potential V_s . It was found that the long narrow channel used in these experiments was the source of a rather large amount of secondary emission of electrons to the collector, especially when the channel was contaminated with potassium from the filament. The secondary emission was, in general, about three times as great as it was in the previous tube. Any electrons liberated by ionization of the gas between S and G are collected on S and show themselves as an additional current in excess of the secondary emission. The primary positive current is measured on the plated P , which is also kept positive (18 volts) to prevent the escape of secondary electrons from the plate into the region between S and G . It will be seen that nei-

Fig. 2. Ionization in helium at various pressures. Ratio of electron current to collector to positive ion current to plate as function of accelerating potential of positive ions.

ther of these collecting potentials can give electrons energy sufficient to ionize helium and by making the plate potential $V_p = 18$ volts, it was possible to prevent escape of electrons from the plate due to photoelectric effect from radiation produced by excited helium atoms. However, these collecting voltages which are higher than those used in previous work with gases of lower ionizing potentials are in excess of the ionizing potentials of most gases except helium; hence they may be a source of ionization by electrons when impurities are present.

In general, the current to the collector S was measured with a gas pressure of less than 10^{-5} mm and then, without changing other conditions, it was again measured with helium present. A series of measurements of the current to S at different accelerating potentials was made at each gas pressure used, and fresh helium was introduced for each new pressure test. Figure 2 shows a series of curves obtained at various pressures by plotting the electron current to the collector (I_s) divided by the positive ion current to the plate (I_p) as a

function of the accelerating potential of the positive ions. Each curve thus represents the efficiency of ionization at various accelerating potentials for each pressure shown (after subtraction of the current due to secondary emission). The lowest curve was taken with pressure 10^{-5} mm or less. It represents the effect of secondary emission alone. The lowest pressure at which a distinguishable effect due to the presence of helium can be detected is 0.01 mm at which the mean free path of K^+ in helium is approximately one-half the distance between the collector and grid. From .01 to 0.1 mm there is definite evidence of ionization. It will be seen from Fig. 2 that the ionization current plus the secondary emission at 0.11 mm amounts to 8 percent of the initial positive ion stream at 750 volts, and the secondary emission with no gas present is equivalent to approximately 2 percent of this current, which leaves 6 percent as the part due to ionization of the gas assuming that the secondary emission is independent of gas pressure. (This assumption may need some modification inasmuch as the secondary emission in the cathode channel may increase due to scattering of the initial positive beam against the metal). We have no way of determining at present how many impacts each positive ion makes between the collector and grid, so that we are not free to predict or calculate the probability of an impact resulting in ionization. However, it appears to be rather small considering that the positive ions at 750 volts have many times the kinetic energy necessary to ionize helium.

There has been some question as to whether the nature of the discharge through the channel into the upper region of the tube does not change materially with the presence of gas in the tube. This point has been tested by measuring the total current between the cathode and filament under all operating conditions of the tube; the only change in this current due to increase of accelerating potential of the positive ions is such as may be adequately accounted for by the increased secondary emission from the cathode itself under action of the ions up to the potential at which an arc occurs. It is possible, however, that a few positive ions of helium might be formed within this region due to electron impact, and these may emerge into the upper region of the tube to cause collisions with the gas present. It is doubtful whether any such collisions would result in ionization, since the escape of an electron from the combined attraction of two positive helium ions cannot be effected as easily as the escape from the field of a K^+ and an He^+ ion. The chief effect of such helium positive ions in the original beam would be to increase I_p , whereas a decrease in I_p is noted with the presence of the gas. This decrease of I_p upon the introduction of gas may be attributed to a slight cooling of the filament due to conduction, or to retardation of the ions by collision with gas molecules sufficient to prevent their reaching P against the retarding potential of V_p of 18 volts. That part of the decrease of I_p due to stoppage of the initial positive ions obviously causes an abnormally large calculated ratio I_s/I_p . This is particularly evident in the curve for 0.11 mm which does not approach zero as rapidly as do the curves taken at lower pressures. The relatively high ratio at 150 volts is due to almost complete stoppage of the initial positive beam, rather than to a greater amount of ionization at this pressure.

A comparison of results obtained from the present tube with those previously reported was made in a test run on neon. Taking due account of the change of position of electrodes and the increased secondary emission in the present tube, the two tubes give quantitative results in good agreement. Figure 3 summarizes the evidence for argon, neon, and helium. N is the number of electrons per initial positive ion per cm path at 1 mm pressure, calculated at the average of the pressure range, 0.05 mm.³ The increase of N with pressure indicates the possibility of ionization of more than one gas atom

Fig. 3. Comparative ionization of argon, neon, and helium by potassium positive ions. N represents the number of ions formed per positive ion per cm path at 1 mm pressure.

by a single positive. At 0.1 mm pressure each positive ion encounters approximately 15 collisions over a path 3.4 cm long on kinetic theory data. This penetration of the positives is not as great as that previously adduced, due to correction of the pressure measurements, but is still comparable with the magnetic analysis experiments of Durbin, Kennard, and Dempster.⁴

The present work will be continued on the investigation of other gases and different positive ion sources. It seems desirable also to test further the effect of impurities upon ionization of the noble gases.

ON THE POTENTIAL RELATIONS IN THE STRIATED POSITIVE COLUMN OF ELECTRICAL DISCHARGES THROUGH HYDROGEN

BY JOHN ZELENY

SLOANE PHYSICS LABORATORY, YALE UNIVERSITY

(Received February 17, 1930)

ABSTRACT

The many lined visible spectrum from the striae in the positive column of a discharge through hydrogen must arise from electronic transitions between excited states having energy levels differing by only about 3 volts for the violet lines. The assumption made by others that the light arises from transitions to the ground level from the lowest excited state of 11.5 volts cannot hold because such transitions would give light in the extreme ultra-violet region only. It is necessary to produce excited states at least 3 volts above the lowest excited level. This requires an energy not far below the ionization potential of 16.1 volts. A process is described by which both excitation of molecules to the required levels and ionization might occur at equal intervals throughout the positive column, but a difficulty arises in the fact that the voltage drop between striae under certain conditions is found to be several volts below the ionization potential. It is assumed that the electrons acquire enough energy for ionization in these cases from collisions of the second kind with molecules of some impurity which are in excited states of comparatively low energy levels. Reasons are given for believing that the impurities involved come from the walls of the discharge tube, and that the walls play a very important role otherwise, as well.

THE periodic changes in the electric force along the length of a striated positive column in a discharge tube are usually taken to indicate that there are periodic positions along the column where ionization is taking place. In fact J. J. Thomson¹ postulates that when the positive column becomes striated it does so because under the given circumstances the periodically changing field which accompanies the striated condition permits the replenishment, with the least total expenditure of energy, of the electrons lost along the path of the discharge either by diffusion to the walls of the tube or by attachment to positive ions or neutral molecules. We should accordingly expect the energies acquired by electrons between striae to correspond at least to ionization potentials.

However, the main part of the light coming from the positive column does not have its origin in the recombination of ions, for there is strong evidence² that there is but little recombination in the body of the gas between electrons and positive ions, owing doubtless to the high prevailing speeds of the former. Such union occurs rather at the walls of the tube.

The light from striae in a discharge through hydrogen gives a many lined spectrum and must originate then in *molecules* in excited states. The

¹ J. J. Thomson, Phil. Mag. 8, 1 (1929).

² See R. Seeliger, Phys. Zeits. 30, 329 (1929).

existence of the periodic changes of light intensity which distinguishes the striated state of the positive column points to the energy acquired by electrons between striae as that corresponding to an excitation voltage. Indeed Grottrian³ using a stream of electrons from a hot cathode in mercury vapor has observed a striated discharge with periodic changes of potential of 4.9 volts, corresponding to the lowest excitation level of mercury. Here, however, there was no ionization occurring throughout the volume of the vapor.

When a cold cathode is used ionization as well as excitation of molecules must be taking place in the positive column and there is then a question how the two effects requiring different voltages are produced at the same equal space intervals along a discharge tube. It seems reasonable to assume that the process requiring the higher energy on the part of the electrons, i.e. ionization, determines the potential fall between the striae, and that the excitation of molecules and subsequent radiation from them is an accompanying action of this first process. According to this view when the electrons in their progress through the field have acquired enough energy for excitation some of them will begin to have inelastic collisions with molecules which raise these to excited states. This action will continue until the electrons which have as yet had no collisions of this kind gain enough energy for ionization after which both kinds of inelastic collisions will take place in the same region along the tube. The probability that at any one impact the collision of an electron with a molecule will be an inelastic one is small and hence the process given is a possible one.

The actual linear distance along a discharge tube in which the above two actions take place need be but a minor part of the whole distance between two striae since the energies required for ionization of a hydrogen molecule and for its excitation to states from which visible light may result are not greatly different. To this is added the fact that the mobility of an ion varies inversely as its motion of agitation and so when the electrons have acquired the most energy from the field their progressive speed along the tube will be the least. Accordingly many more impacts than elsewhere will here occur within a given length of the discharge tube and nearly all of the electrons will have their inelastic collisions inside a short length of the tube from which they will then begin a new excursion. Some addition must be made to this process because under some conditions the potential drop between striae is less than the ionization potential.

Compton, Turner and McCurdy⁴, who have expressed views regarding the process of stria formation which in some respects are similar to those above, have assigned an important role to impurities in the gas which are so essential for the appearance of striae in nearly all gases. They postulate that the function of the impurities is, by collisions of the second kind, to restore to the stable form such metastable excited atoms which, having diffused to all parts of the interstria spaces, would otherwise after inelastic impact with comparatively slow electrons give rise to radiations there and thus tend to wash out the visibility of striae.

⁴ K. T. Compton, L. A. Turner and W. H. McCurdy, *Phys. Rev.* **24**, 597 (1924).

Günther-Schulze⁵ also visualizes the procedure by which the electrons in a discharge tube give up their acquired energy in inelastic impacts within periodic narrow zones in much the same way as that described above, but inasmuch as under some conditions the fall of potential between striae is less than the ionization potential he assumes that the ionization process is not related to stria formation and that ionization arises from a separate set of fast electrons evidence of whose existence has been given from spectroscopic data by Seeliger and Okubo.⁶ Günther-Schulze believes that striae are formed as a result of the inelastic impacts in the narrow zones named of a slower set of electrons which raise the molecules to the lowest excitation level; and seeks support for this view from the fact that under some conditions the energy acquired by electrons between striae in hydrogen has a value nearly equal to this excitation potential. Unfortunately an excitation of molecules to the first levels in hydrogen does not suffice to explain the luminosity of the striae which is observed, as will be shown below.

A comparison of the magnitudes of the energies required for the ionization and for the excitation of hydrogen molecules with the measured potential drops between striae evidently deserves special consideration.

The ionization potential of the hydrogen molecule, which takes place without dissociation, is given⁷ as 16.1 ± 0.2 volts and the energy required to raise a hydrogen molecule to the lowest excited level is given as 11.5 ± 0.4 volts. Above the lowest excitation level there are a large number of other levels extending according to Richardson⁸ to about 15.1 volts.

In the light from striae the visible part of the spectrum must result from transitions between excited states since a transition from any excited state to the $1^1\Sigma$ state would give a line far down in the ultra-violet. To obtain the violet end of the spectrum we must start with an excited state at least 3 volts above the lowest excited level of 11.5 volts, i.e. at 14.5 volts or more.

In some recent measurements⁹ I found the potential drop between striae in hydrogen at pressures below 0.5 mm to be approximately 12 volts and even lower values have been obtained by others. If in this region of pressures the electrons possess only the energy gained directly from the field between adjacent striae, how then is it possible for them to ionize the molecule or to excite it to a sufficiently high level to give rise to the visible spectral lines which are observed? It might be urged that perhaps the ionization in the gas is confined to molecules of traces of impurities having a lower ionization potential than those of hydrogen, but the argument cannot be used to explain directly the production of a hydrogen spectrum. It seems necessary therefore to invoke the aid of some other process. We might postulate, since the electrons are not able to obtain the requisite energy in the potential drop between adjacent striae, that they carry energy from one stria distance into the next,

only a part of them losing their energy by inelastic impact in any one stria. It is difficult, however, to imagine how such a process could bring about a periodic appearance of light.

It seems more plausible to assume that the electrons get the energy needed for ionization or excitation, over and above that acquired from the field within a single stria distance, by collisions with molecules of some impurity which are in an excited or metastable state requiring less energy than is requisite to excite a hydrogen molecule. There is good theoretical ground and some direct evidence¹⁰ for the possibility of an electron having its energy increased by this sort of a collision of the second kind. By the presence of traces of impurities of different kinds and in different amounts might be explained the widely different minimum values obtained for the potential drop between striae under different circumstances and by different observers.

In support of the above view it may be mentioned that Pentscheff¹¹ found in very pure hydrogen that, while the potential fall in a stria diminished with reduction of pressure for a constant current, it at no time got below 20 volts, whereas in slightly impure hydrogen it fell to 13 volts under the same circumstances. The pressures used are not stated but if the lowest values of the potential which are given were obtained at pressures below 1 mm, the energy gained between striae by electrons in pure hydrogen were more than sufficient for the ionization of hydrogen molecules, whereas in the impure hydrogen it is necessary to assume that the electrons acquired some energy from secondary processes, such as the one described above, to explain the observations.

Then too, my recent measurements show that when the hydrogen gas was kept stationary and not renewed the energy acquired by electrons in their passage through a stria at any pressure is one to two volts less than when the gas in the discharge tube was being continuously renewed. We should expect a larger amount of impurity to be present in the gas in the first case cited since impurities dislodged from the walls of the tube by the action of the discharge would accumulate in the tube when the gas was not being renewed.

The amount of foreign gas liberated from the walls would naturally depend within some limits on the magnitude and time of action of the discharge current, and according to the view expressed above the potential fall between striae should accordingly diminish as the discharge current is increased. This is actually in accord with my own observations as well as those of Holm, Wehner, and Neubert.¹²

Pentscheff¹¹ also found a decrease in the potential fall between striae with increase of current when impure hydrogen containing mercury vapor and other gases coming from the walls of the tube was used, but when very pure hydrogen was used and great care taken by prolonged treatment to free the

metal parts and the walls of the discharge tube of occluded impurities the potential fall between striae rather increased somewhat as the discharge current was increased.

Again, when discharges of the same current density are sent through two tubes of different diameters we might expect the amount of impurity liberated per unit surface of the walls to be approximately the same and inasmuch as the larger of the tubes has a larger ratio of volume to surface the concentration of the impurities liberated from the walls would be greater in the smaller tube. We should then expect the potential fall per stria to be smaller in the smaller tube, and this was found to be the case in my recent measurements.

When the pressure of the gas in a discharge tube is increased a discharge through the tube is less effective in liberating occluded impurities from the walls and such as are liberated form a smaller proportion of the gas than would be the case at a lower pressure. If the amount of these liberated impurities tends to decrease the potential fall between striae then this fall should decrease with decrease of pressure and such was the relation I actually found⁹ both with a stationary gas and with the gas flowing continuously through the discharge tube.

Neubert¹² found that when all spectroscopic traces of mercury disappeared from the discharge through hydrogen the potential fall between striae was 11 volts at the lowest pressure used although previously when this condition was not fulfilled the values obtained were as low as 7.5 volts. Mercury molecules which appear in this instance to lower the potential fall between striae in hydrogen do not possess excitation levels low enough to account for the facts in all cases. However among other likely impurities to be found in discharge tubes there is for example oxygen whose molecules possess metastable states of energy less than 2 volts.

The evidence which has been presented in favor of the view that the liberation of impurities from the walls of the discharge tube by the current is an important factor in determining the variations of the potential fall between striae which have been observed under various conditions, is to be sure for the most part circumstantial evidence.

In connection with the experimental result that the energy acquired by electrons in their motion between two striae increases as the pressure increases, it should be emphasized that there is evidence which indicates that electrons in collisions with molecules may lose more energy than would result from purely elastic collisions and which loss alone I considered in computing the energy acquired by electrons from the observed potential fall between striae. By such greater losses if of the proper magnitude might be explained the increase with pressure in the observed potential drops between striae, but the assumption of these larger losses introduces other difficulties and does not help to explain most of the other observed variations studied.

Another factor that may have some influence on the striated discharge consists of the gas convection currents always present in these discharge

tubes. It is believed however that most of the causes that affect distances and potential drops between striae center about the walls of the tube. These walls, under electronic bombardment during a discharge or with change of pressure or temperature, release occluded molecules of the principal gas and those of foreign substances. They destroy the metastable states of molecules which impinge upon them. They are the seat of the main portion of the recombination of ions and electrons which occurs in the discharge tube, giving rise thereby to electric currents from the axis of the tube towards these walls. Electric charges which collect on the walls influence the electric field in the neighboring gas; and electrons in collision with the walls may lose more or less of their energy depending on the state of the surface of the walls. The differences between the numerical results of different observers on stria distances and the potential fall between striae in discharge tubes can best be accounted for by assuming them due to effects of different conditions at the walls of the tubes. Full equilibrium conditions at the surface of these walls are at best very slow of attainment especially where the gases inside of the body of the glass are concerned. Even if by special treatment such an equilibrium is attained and concordant results obtained in a given case, the nature of the essential elements in equilibrium might still remain unknown.

ON THE DISTRIBUTION IN TIME OF THE SCINTILLATIONS PRODUCED BY THE α -PARTICLES FROM A WEAK SOURCE

BY N. FEATHER*

PHYSICAL LABORATORY, JOHNS HOPKINS UNIVERSITY, BALTIMORE

(Received February 18, 1930)

ABSTRACT

The course of radioactive transformation, which in all known cases takes place in strict conformity with an exponential law of decay, is most satisfactorily explained on the supposition that individual atoms disintegrate in complete independence one of another, so that the disintegrations throughout an extended source constitute a perfectly random series of events. Many observations favor this conclusion, but experiments have recently been described showing that at high concentrations (Kutzner) and also at very low concentrations (preliminary work of Pokrowski) departures may occur. An experiment is here described in which the record of more than 10,000 scintillations produced by the α -particles from a weak source of polonium has been obtained and analysed. A large solid angle was effective, as in Pokrowski's experiments. The various corrections to be applied to the immediate data are discussed: in the present case they were of no importance. There was no evidence to show that the Marsden-Barratt distribution formula was not completely valid under the conditions obtaining.

An investigation was also made of the effect of intense γ radiation on the rate of disintegration in a weak source (Pokrowski), with entirely negative results.

INTRODUCTION

A SERIES of exactly similar point-events separated from one another in time but limited to a prescribed small region of space is defined as a "random" sequence when the probability of occurrence of one such event is the same for equal small intervals of time irrespective of the temporal locations of those intervals. For series comprising point-events separated in space as well as in time, or of line-events having a common focus whilst being separated in time, a further condition must be satisfied if the events are to be considered as taking place "completely at random." In the former case, in any given interval of time, the probability of occurrence of a single event must be the same for equal small elements of volume, irrespective of the spatial locations of such volume elements—and, in the latter, equal probabilities must characterise equal small elements of solid angle about the focus no matter what the directions of the axes of the elementary cones considered.

Radioactive disintegration in an extended source of active material may be regarded as a phenomenon involving line-events originating in foci themselves distributed in space. Now, macroscopically examined, all such cases have been found to exemplify a common transformation law and the customary interpretation of this fact has been based on the assumption that,

* Fellow of Trinity College, Cambridge. Associate in Physics, Johns Hopkins University.

in as far as concerns its time relationships, the ultimate atomic process occurs entirely at random. If this be assumed then the spatial distribution of disintegrating atoms in an extended source must also be a random one—and the observed distribution of directions of particle (or quantum) emission likewise random, for here, whilst preferential directions with respect to natural atomic axes are not excluded, in any practical case the random distribution of atomic axes in space would completely mask such regularities if in fact they were present.

Whilst this is the logical conclusion to be drawn from the usual interpretation of exponential decay, where the analysis is carried down to the behavior of individual atoms, it has been variously maintained that the phenomena observed on the macroscopic scale require no further "explanation" than that the time-distribution of disintegrations in a radioactive source, considered as unit, shall be a random one. From this point of view there remains the possibility that the complete randomness which we have considered may be found lacking under a more penetrating analysis. However unsatisfactory such a contention may appear, from the physical standpoint—and whether or not we hold the view that it is even permissible when the whole range of macroscopic experiments is considered¹—the fact remains that a number of careful experiments has been made and that some of them point to departures from a time-randomness under certain conditions of observation.

For the type of statistical analysis here involved two methods are available, based upon the Bateman² and the Marsden-Barratt³ formulae respectively. In either case a graphical means may be employed in the final comparison of experiment with theory, and, when this is done, conclusions appear more obviously in the latter case, since theoretically a linear function is predicted. But the Bateman type of analysis possesses the compensating advantage that a numerical criterion is afforded of goodness of fit by the dispersion coefficient which may be calculated from the experimental data themselves. Both methods have been used in practice. Kutzner⁴ has made a very thorough analysis of the data afforded by three series of observations automatically recorded under as nearly as possible identical conditions of operation of an electrical point counter. The sole difference between the series (which had reference to 7761, 6907 and 5923 particles, respectively) lay in the surface concentration of polonium in the radioactive source employed. Here there was a factor of 25 times as between conditions in the first and third series, the actual concentrations being roughly 2×10^{-4} , 8×10^{-4} and 5×10^{-3} equivalent milligrams per cm^2 , respectively. With the weakest source no appreciable deviation from perfect time-randomness

¹ In the writer's opinion the only evidence which the macroscopic experiments fail to supply is evidence for the random distribution in space of the disintegrating atoms in a given source. The exponential law of decay may be deduced alike from measurements made on the radiation emitted within a small or a large solid angle about such a source.

⁴ Kutzner, *Zeits. f. Physik* **44**, 655 (1927).

was found, but, with the other two, deviations quite outside the limits of probable error were set in evidence. In each case dispersion was subnormal (Bateman analysis), there being a marked lack of the longer time intervals between observed disintegrations (Marsden-Barratt analysis). The extent of the discrepancy increased with the surface concentration in the source. Whilst leaving the full interpretation until fresh data had been obtained using large solid angles (only about 1/400 of the total emission was originally employed), Kutzner concluded that his results were in agreement with those of Curie,⁵ who found complete accord between experiment and theory with polonium sources of (apparently) very small concentration. The experimental material in this latter case consisted of 9974 measured time intervals belonging to four distinct series of measurements.

Recently Pokrowski⁶ has published an account of preliminary observations with very weak sources and large solid angles. The concentration employed was about 10^{-7} equivalent milligrams per cm^2 . It is not stated what material was used. Data having reference to 1633 time intervals, analysed by the method of Marsden and Barratt, showed an excess both of the very short and the very long intervals and no real agreement with theory over any appreciable range. In the discussion it was pointed out that new phenomena at small concentrations might be expected if at the higher concentrations mutual action between neighboring nuclei was possible. On account of the fundamental nature of such a suggestion, and because a suitable source of polonium of small concentration was readily available, it was thought worthwhile to make a series of observations parallel to those of Pokrowski, using the scintillation method of registration as he had done. Moreover, the writer did not feel compelled to make the present investigation exhaustive—covering a wide range of surface concentrations—most especially because it is explicitly stated by Pokrowski that his report is merely preliminary in scope. Rather is it intended to put forward this restricted series of results, only, as independent evidence, for what it is worth.

EXPERIMENTAL METHOD AND RESULTS

As a source of α -particles for scintillation experiments polonium is in many respects most suitable: it is not accompanied by appreciable β or γ radiation, and its period is sufficiently long for the decay generally to be negligible. However, when experiments extending over a number of weeks are in question, the latter condition no longer holds⁷ and the desired constancy can be retained only by employing sources of radium *D*, *E* and *F* in equilibrium. Now the writer possessed some pieces of gold leaf exposed to radon in May 1929.⁸ In January 1930 calculation showed that their α -

⁵ Curie, *J. Physique* 1, 12 (1920).

⁶ Pokrowski, *Zeits. f. Physik* 58, 706 (1929).

⁷ The type of "uncorrected" distribution of time intervals which would be obtained in the Marsden-Barratt analysis of data referring to a source of varying activity is one in which very short and very long intervals are each in excess of the number calculated theoretically for a constant source of the same average activity.

⁸ See Feather, *Proc. Camb. Phil. Soc.* 25, 522 (1929).

particle activity was still increasing—but sufficiently slowly for this material to be considered a constant source of α -particles for the present type of experiment over a period of two or three weeks.⁹ It was decided, therefore, to employ it in the work to be described. By placing the gold leaf directly in contact with the zinc sulphide screen a solid angle of approximately 2π radians could simply be attained. Preliminary tests showed, however, that the activity of the source was 5 or 10 times too great for convenient counting. A reduction was made as follows: one surface of a flat piece of glass was very lightly ground with fine emery. A small piece of the activated gold leaf was placed upon the ground surface and, by means of the smooth rounded end of a glass rod, used as a small pestle, was gradually ground to an extremely fine deposit of gold dust which adhered to the roughened surface. The zinc sulphide screen, supported on a microscope cover glass, was then fastened in position in contact with the ground surface. On the free upper surface of the cover glass was fastened a piece of thin aluminum foil, pierced with a hole of approximately 1 mm^2 area, which served to limit the portion of screen under observation. The microscope used was built up of a Watson's Holoscopic objective, of numerical aperture 0.45 and focal length 16 mm, and a low-power eyepiece, giving a field of view of about 8 mm^2 area. The source system was supported so that the hole in the aluminum foil was central in the field of view and, during periods of observation, a dim red light produced a faint illumination of the foil, leaving the central portion of the field relatively dark.¹⁰ The mean interval between scintillations was somewhat greater than 3 sec.¹¹

The record itself was made with the aid of a drum chronograph with magnetically controlled pen, the drum being driven at a uniform rate by the combination of falling weight and centrifugal governor. The uniformity of rate was tested from time to time and found altogether satisfactory. Throughout the presentation of the results, for sake of simplicity, time intervals have been replaced by linear intervals; the conversion factor from the one to the other is 0.921 cm/sec.

Observations were spread over thirteen consecutive days; on each day two or three "sessions"—30 "sessions" in all. During each session "periods of observation" alternated with periods of rest, each, on the average, about a minute and a half in length: in all, 334 "periods of observation." During each period about 30 scintillations were recorded; altogether 10134 "intervals" between scintillations were measured. In the treatment of the records periods were measured to the nearest millimeter and the number of intervals in each period was counted. From this material the mean interval, ω , was determined. Intervals were measured in millimeters and entered in a statistic according to their length. In the first analysis grouping was in millimeter ranges, the elementary group containing those intervals of which

⁹ A more complete statement on this question is reserved for the discussion.

¹⁰ Cf. Chariton and Lea, *Proc. Roy. Soc.* 122A, 304 (1929).

¹¹ From the figures given by Pokrowski it would appear that his field of view had an area of about 70 mm^2 and that the mean interval in his experiments was roughly 0.8 sec.

the length lay between x and $x+1$ mm. Later these groups were combined in sets of three and values of n_x obtained, where n_x now represents the number of intervals of length between $x-1.5$ and $x+1.5$ mm. Values of N_ξ followed immediately from this series of numbers; here N_ξ is the number of intervals of length greater than ξ mm. Now the formula of Marsden and Barratt may be written

$$N_\xi = N_0 e^{-\xi/\omega} \quad (1)$$

or

$$\log_{10} N_\xi = \log_{10} N_0 - (0.4343/\omega)\xi. \quad (2)$$

In our case $N_0 = 10134$ and $\omega = 31.28$ mm. Thus the theoretical distribution leads to the straight line

$$\log_{10} N_\xi = 4.0058 - 0.01388\xi. \quad (3)$$

This line is plotted together with the experimental points in Fig. 1. In Fig. 2 values of $\log_{10} n_x$ are plotted (A).

Fig. 1.

To a first approximation

$$n_x = -3(dN_\xi/d\xi)_x. \quad (4)$$

If this relation were strictly correct it is obvious from (1) that the graph of $\log_{10} n_x$ would be a straight line of the same slope as (3). A simple calculation shows that in fact a small correcting term ϵ is involved, depending on the ratio of the "plotting interval" (in this case 3 mm) to the mean length ω (here 31.28 mm), in such a way that

$$n_x = -3(1+\epsilon)(dN_\xi/d\xi)_x. \quad (5)$$

The condition of parallelism therefore remains, but the line as a whole is shifted slightly. Introducing numerical values we have

$$\log_{10} n_x = 2.9875 - 0.01388x. \quad (6)$$

This line is included in Fig. 2 for comparison with the experimental results. The straight line *B*, Fig. 2, corresponds to a plotting interval of 30 mm. Its equation, deduced in like manner to the above, is

$$\log_{10} \nu_x = 4.0039 - 0.01388x. \quad (7)$$

The corresponding points have been obtained by grouping the values of n_x in sets of ten—and the results are presented in this form, also, chiefly in order that they may be more nearly comparable with those of Kutzner, already referred to.

Fig. 2.

DISCUSSION

Any consideration of the results here set forth must be twofold in character: there is the comparison of experiment with theory and, in addition, that of the present experimental results with those of previous investigators. But, before either comparison is made, it is necessary to consider what corrections, if any, should be applied to the crude observational material which the experiment provides—for the points plotted in Figs. 1 and 2 have been deduced without any corrections at all from the measurements of length on the chronograph record. First there is the varying activity of the source, which is entirely apart from any question of imperfection in the methods of registration. Depending upon the extent of this variation the theoretical logarithmic plot will depart more or less from the ideal straight line. At the time of the observations the strength of the source was in-

creasing daily by about 0.205 percent. Columns 1 and 2 of the accompanying table show how observations were spread over the thirty sessions on the thirteen days during which the experiment was in progress. They indicate that the mean interval ω , deduced from the full material, corresponds most probably to the true mean interval on the eighth day. Column 4 gives the true mean interval corresponding to each successive day calculated on this basis and column 3 the observed mean values obtained from the daily observations. Column 5 will be referred to at a later stage in the discussion. With the material which the table provides we may proceed to calculate the theoretical form of $\log_{10} N_t$ in the present experiments, which in the ideal case of the constant source was represented by Eq. (3). For each day's results the theoretical distribution is calculated from Eq. (1) using the

TABLE I.

1	2	3	4	5	1	2	3	4	5
Day	Number of intervals	Mean interval mm	True mean interval mm	Probable error mm	Day	Number of intervals	Mean interval mm	True mean interval mm	Probable error mm

appropriate value of ω . The individual distributions are then combined. When this somewhat laborious procedure was carried through it became evident that the greatest departure from the straight line of Eq. (3) was so slight as not to be appreciable on a diagram drawn to the scale of Fig. 1.

The second correction concerns the failure of the method of registration when scintillations succeed one another in rapid succession. It is not that scintillations are missed, but the actual time intervals are distorted on the record obtained. The first point in Fig. 2 (A) has reference to intervals of apparent length less than 3 mm (i.e. intervals shorter than 0.32 sec.): 988 measured intervals were distributed as follows; 0-1 mm, 0; 1-2 mm, 404; 2-3 mm, 584. Assuming, to a first approximation, that the number 988 is the true number of intervals in the three sub-groups in question we should expect a distribution giving 0-1 mm, 340; 1-2 mm, 329; 2-3 mm, 319 inter-

vals, respectively. Thus errors of registration have resulted in an apparent increase of length in the shortest intervals, and this must necessarily have been counterbalanced by an apparent decrease amongst the remainder. The figures quoted do not allow us to make any definite statement about the errors actually committed. At the one extreme is the supposition that in no case has the error been greater than 1 mm. On this basis we should assume that 340 intervals actually between 0 and 1 mm were recorded as between 1 and 2 mm in length, whilst 265 actually between 1 and 2 mm were recorded as between 2 and 3 mm long. At the other extreme is the supposition that all the intervals in the second and third groups in reality were correctly registered, the error lying entirely with the intervals of the first group. Then 75 members of that group could have been wrongly assigned to the second group and the remaining 265 members to the third. From the first point of view, amongst the total number of 10134 measured intervals (including the 988 shortest intervals with their newly assigned lengths) the correction of 605 1 mm errors of underestimation is necessary to rectify the crude distribution: from the second point of view the correction of 75 1 mm and 265 2 mm errors of underestimation is required. On account of the small fractions of the total which these numbers represent the two methods of correction lead to almost identical results. The former transfers 18.9 intervals from $n_{1.5}$ (originally 988), the second 19.4 intervals; these are effectively distributed amongst the various values n_x in gradually decreasing shares as x increases; thus $n_{4.5}$ is increased by 2.9, $n_{7.5}$ by 2.3 intervals, and so on. In Fig. 2(A) the change in position of the first point only is appreciable, as the figure indicates—and obviously to carry this correction to a further approximation is unnecessary.

From the above considerations, therefore, we may conclude that the experimental points of Figs. 1 and 2 and the straight lines accompanying them are entirely comparable: agreement between experiment and theory is to be measured by the closeness of fit of the points and the corresponding straight lines.

It must be admitted at the outset that the fit is good, though hardly as good as in the experiments of Curie.⁵ On the other hand, by comparison with the results of Kutzner,⁴ it will be seen that no such systematic deviations as he observed are in evidence here. It was not to be expected that they should be, since the concentration of active material in the source was smaller than the least concentration which Kutzner employed. Fig. 2 (B)—closely comparable with Figs. 2 (b), 3 (b) and 4 (b) in his paper—shows excellent agreement for the first five points and a non-systematic deviation later. Kutzner's figures likewise have five points closely on the theoretical straight line but, for his two stronger sources at least, the sixth and seventh points lie progressively below the line. Finally, making comparison with Pokrowski's results,⁶ it is evident that no deviation of the order of magnitude of that reported by him is here present, though such deviation as there is in the earlier portion of Fig. 1 is certainly in the same sense as that which he observed. But the order of magnitude is entirely different. It is true that

in the present experiments the surface activity of the source was roughly twenty times as great as in the experiments of Pokrowski, but it must be emphasised that this is a macroscopic comparison. When the phenomenon of aggregation is taken into account it is obvious, for instance, that the size of the mean aggregate does not increase as rapidly as does the mean surface density of deposit during a single activation process, since new centers of aggregation presumably appear continuously throughout the process. Now it is unquestionably the size of the aggregates which is of importance for theories of the mutual action of neighboring atoms. Moreover it is almost impossible to make any *a priori* statement concerning aggregation when the mode of activation is different in the two cases to be compared.

It was pointed out earlier in the discussion that variations in the activity of the source, if sufficiently great, would lead to deviations from the theoretical distribution of the type of which Fig. 1 offers very slight indication and Pokrowski's results very marked evidence indeed. It has already been demonstrated that such changes cannot account for a non-linear relation in the present experiments, but it must be borne in mind that the same effect would be shown with a constant source and a varying efficiency of registration. It is very probable that this explanation is likewise inadequate. Column 5 of Table I gives the probable error in the thirty observed values of the mean interval and asterisks mark those cases in which the latter value differs from the true value (column 4) by more than the probable error. It will be seen that there are ten such cases as against twenty cases of closer agreement than that which the limits of probable error represent. Thus we are dealing with a set of observations more than normally uniform, and it is therefore unlikely that variations in registration efficiency are here in point.

Finally, in order to make sure that simple errors in length measurement were not vitiating the results, the total period of observation was deduced in two ways; first by adding together the measured lengths of the 334 periods, secondly by adding together the measured lengths of the 10134 intervals. In the latter addition the supposition was made that each interval classed as between x and $x+1$ mm in length was actually $x+0.5$ mm long. The first addition led to the value 316988 mm, the second to 317032 mm—a difference of one part in 7200. Moreover, the second sum would be expected to be slightly the larger of the two on account of the simplifying assumption introduced.

A FURTHER EXPERIMENT—THE EFFECT OF INTENSE γ RADIATION

In the account already referred to Pokrowski⁶ has described a very remarkable experiment in which the irradiation of a weak source of radioactive material with γ -rays was found to produce an increase of 45 percent in the frequency of the scintillations observed. X-ray irradiation was reported to produce a similar effect. It was suggested that the possibility of such an effect was intimately connected with the use of a very weak source, in which the hypothetical mutual action of neighboring atoms was too small to be

effective. From this point of view the null result of earlier experiments with stronger sources was obviously explicable.¹²

There should, of course, be an intermediate case with sources a little stronger than Pokrowski's. The writer has carried out the analogous experiment employing a somewhat more concentrated source. To this end the arrangement of the previous investigation was modified in certain particulars; for instance it was no longer thought necessary to employ the maximum possible solid angle and it was recognised that it would be a great convenience to be able to remove the source from time to time. The latter was therefore carried on a rectangular glass plate (a fragment of the original gold leaf was attached to the smooth surface by means of a very thin film of castor oil) which when placed in its holder was maintained in a perfectly definite position, about 1.5 mm distant from the zinc sulphide screen. An area of about 2 mm² of screen was under observation. In the new arrangement the field illumination resulted in the screen being dimly lighted and the rest of the field relatively dark. This is an advantage, for, under sufficiently intense γ -ray irradiation, the screen becomes self-luminous and it is advisable to make conditions in the control experiment as nearly equivalent as possible.

The first comparison was made with a radon tube containing about 25 equivalent milligrams of emanation¹³ placed on the axis of the system about

¹² When the present account was in the final stages of preparation Pokrowski's second paper (*Zeits. f. Physik* 59, 427 (1930)) appeared in this country. In it a more detailed point of view is adopted and experimental data, obtained with a source of radium together with its subsequent products, put forward in its support. However, the experiments newly described differ in essential particulars from those of the writer, so that there is at present no basis of comparison. Nevertheless it may be remarked that if, as Pokrowski assumes, this process of induction is "saturated" in the ordinary case of a concentrated source, and if the mechanism is similar to that which he suggests, then the α -particles from such a source would not be homogeneous in velocity, but a distribution of velocities greater than the normal would also be present.

¹³ The writer desires to thank Dr. C. F. Burnam of the Kelly Hospital, Baltimore, for providing him with this material.

3.7 cm distant from the source. The mean length of 1240 intervals recorded with the tube in position was 9.18 mm, 1181 intervals recorded when the tube was removed gave 9.33 mm. Within the probable error of the measurements, therefore, no difference was found. With this arrangement, however, the β and γ -ray luminosity of the screen was almost inappreciable and a further comparison was determined upon with more intense irradiation. The γ -ray tube was moved up in contact with the glass plate supporting the source.¹⁴ Under these conditions the zinc sulphide screen fluoresced brightly and observations with the γ -ray tube in position¹⁵ invariably led to greater values of the mean interval than those carried out when the tube had been removed. It was obvious that scintillations were being missed under the former conditions of observation. Table III summarises the comparisons made on successive days as the activity of the γ -ray tube decayed. A constant geometrical arrangement was used throughout. The strength of the γ -ray source is given in column 1. Columns 2 and 5 show the numbers of intervals

Fig. 3.

measured, in the first case with the γ -ray tube removed, in the second case with the tube in position. Columns 3 and 4 give the values of the mean interval deduced from these measurements. When the γ -ray activity had fallen to 4.6 equivalent milligrams the brightness of fluorescence which it caused was roughly the same¹⁶ as the brightness of artificial illumination employed when the tube was absent; thereafter the very weak fluorescence with the tube in position was supplemented by a certain amount of artificial illumina-

¹⁴ The thickness of the plate was 1.8 mm. The radon tube was contained in a brass case about 0.7 mm thick.

¹⁵ The polonium source was exposed to the γ -rays only during the periods of observation, amounting to about half an hour daily.

¹⁶ This comparison is necessarily inaccurate on account of the difference in quality of the light in the two cases.

tion also. In Fig. 3 the results are shown graphically. The lengths of the vertical lines indicate the magnitude of the probable error in each case. The gradual increase in the α -particle activity of the source during the period of the observations is clearly evident from the decrease in the mean interval determined with the source alone.¹⁷ The broken line, which represents sufficiently well the trend of the apparent activity of the source under γ -ray irradiation, has been drawn in such a way that the difference between corresponding ordinates on this and on the full line, respectively, decreases according to the same law as the activity of the radon tube employed as the source of γ -rays. Whilst no great emphasis is laid on this way of exhibiting the results,¹⁸ it does show at least that, as long as the effect is relatively slight the percentage of scintillations missed when observations are carried out in the presence of intense γ radiation is roughly proportional to the strength of that radiation.

Throughout the present experiments the observed effect of the irradiation of the source has been an apparent decrease in its α -particle activity. It was thought possible, however, that over a short period, during the decay of the γ -ray source employed, an apparent increase would be found. This might have been expected when the intensity of the residual primary β -particles and the secondary electrons produced by the γ -rays was just of the right order of magnitude to give rise to the type of multiple- β -particle scintillations described by Chariton and Lea.¹⁹ Probably the requisite β -particle intensity was reached sometime between the tenth and the fifteenth day, but it is very doubtful indeed whether any trace of this phenomenon has been observed in the present case. Chariton and Lea, observing with a microscope of numerical aperture 0.65, classify this type of scintillation as very faint: it seems likely therefore that, observed with a less powerful microscope, they would only be recorded occasionally when α -particle scintillations were present as well.

In conclusion, therefore, it may be said that no effect has been observed which can in any way be attributed to the induction of disintegration in the polonium nucleus by any of the γ -rays of radium B+C. Very obviously this statement refers only to the concentration of source here employed, but it is interesting to remark that supposing a 10 percent effect had been observed at the beginning of the experiment, when the γ -ray source was most intense, then that would have corresponded to a reaction with the nucleus more than a million times more probable than the recognised types of reaction with the extra-nuclear electrons—and, moreover, this calculation is based on the supposition that γ -rays of all wave-lengths are capable of producing the nuclear change. The factor would be even greater if a selective effect were involved.

¹⁷ In most cases observations with the source alone were carried out immediately after those under conditions of γ -ray irradiation. Occasionally this order was reversed, as may be seen from the figure, but without any systematic difference appearing.

¹⁸ It may be remarked, for comparison with the earlier discussion, that of the 14 points belonging to each curve in Fig. 3, in each case 9 fall within the limits of probable error and 5 fall outside those limits.

THE L SERIES SPECTRA OF THE ELEMENTS FROM CALCIUM TO ZINC

BY C. E. HOWE

DEPARTMENT OF PHYSICS, OBERLIN COLLEGE

(Received February 4, 1930)

ABSTRACT

Using the first inside order of a plane grating (600 lines per millimeter) L lines of the elements Zn, Cu, Ni, Co, Fe, Mn, Cr, V, Ti and Ca have been measured. Separation of the L_α and L_β lines as well as the L_i and L_η is attained by adjusting the grating so that the angle between the inside order and the plane of the grating is small. Under this condition the angular dispersion is given by $(d\alpha/d\lambda) = (1/D\beta)$, where D is the grating space and β the small angle between the plane of the grating and the first inside order. The results obtained are somewhat higher than those obtained by crystal measurements but are entirely consistent with the work of other experimenters. The failure of the L_α and the L_β lines to appear in the case of calcium is in accord with Foote's extension of Stoner's arrangement of the electrons. All measurements are absolute.

THE study and measurement of x-rays of long wave-length have been handicapped by the extensive absorption in air of the rays and by the lack of satisfactory gratings, the grating spaces of ordinary crystals being much too small. The former difficulty has been overcome by the use of vacuum spectrographs; the latter to a certain extent by the use of organic crystals of large grating space. Extensive measurements of L lines in this region have been made by Thoraeus.¹ His work was done with a vacuum spectrograph using crystals of lauric acid ($2d = 54.536\text{\AA}$) and palmitic acid ($2d = 70.98\text{\AA}$). The wave-lengths given in his report are based on the sodium K_α line (11.884\AA). Shearer² has measured the nickel L_α line using the 100 face of a crystal of cane sugar ($2d = 21.1519\text{\AA}$). Unfortunately, however, absorption in the crystal causes a considerable broadening of the spectral lines. It is also quite conceivable that the index of refraction might take on anomalous values due to a resonance frequency of the electrons in the crystal being near the frequency of the x-rays. Under these conditions the application of Bragg's law becomes uncertain even in its corrected form. For these reasons it seems advisable to apply the recently developed method of measuring x-ray wave-lengths from spectra obtained by reflection from a ruled grating to the study of the L lines under discussion.

When Professor A. H. Compton³ showed in 1923 that x-rays could be reflected from plane surfaces at grazing angles smaller than a certain critical angle determined by the index of refraction of the x-rays reflected, he opened

up the possibility of using a ruled surface as a grating. Two years later Compton and Doan⁴ obtained x-ray spectra from a ruled reflection grating. In 1926 and 1927 Thibaud,⁵ Osgood,⁶ and Hunt⁷ applied the ruled grating to the study of the spectral region between x-rays and the ultra-violet, Osgood using a concave grating with a Rowland mounting. Since then the grating has been used by a number of investigators⁸ in this field, some making the wave-length determinations from the constants of the apparatus, others by comparison with lines of known wave-length. This method has been used⁹ to compare wave-lengths as measured by crystals with those measured by gratings. The measurements from gratings, using the constants of the apparatus, have been found slightly greater than the crystal measurements.

The general method used in the spectroscopy of soft x-rays has been reviewed by Osgood.¹⁰ The general methods and results of this experiment were briefly presented by the author¹¹ to the American Physical Society. Kellström¹² has reported on measurements of the lines in this same region using outside orders of the spectral lines, comparing them with the K_{α} line of aluminum.

THEORY OF THE EXPERIMENT

In making wave-length measurements in the optical region using a plane reflection grating the formula $n\lambda = D(\sin \phi - \sin \phi')$ is used, n being the order observed, λ the wave-length in centimeters, D the grating space in centimeters, ϕ the angle of incidence and ϕ' the angle of diffraction. In using the plane grating for measurements in the x-ray region it is more convenient to express the wave-length in terms of the grazing angle of incidence θ and the grazing angle of diffraction $\theta \pm \alpha$, the negative sign referring to inside orders, in which case,

$$n\lambda = D[\cos \theta - \cos (\theta \pm \alpha)]. \quad (1)$$

By a simple trigonometric transformation this becomes

$$n\lambda = 2D \sin \frac{2\theta \pm \alpha}{2} \sin \frac{\alpha}{2}. \quad (2)$$

Reference to Fig. 1 will help to visualize these angles. The beam of x-rays collimated by the slits, falls on the grating. The zero order is reflected to the point *R*, the first outside order to the point *O* and the first inside order to the point *I*. *P* is in the extended plane of the grating, while *D* is the position of the direct beam when the grating is removed.

It should be noted that the position of the inside order is farther removed from the zero order than is that of the first outside order, indicating greater angular dispersion for the inside order. Differentiating Eq. (1) with respect

Fig. 1.

to α there is obtained the expression $n(d\lambda/d\alpha) = D \sin(\theta \pm \alpha)$ where, as before, the plus sign refers to outside orders and the minus sign to inside orders. The angular dispersion may be written as

$$\frac{d\alpha}{d\lambda} = \frac{n}{D} \frac{1}{\sin(\theta \pm \alpha)}.$$

It is thus seen that the dispersion is greater for inside orders than for outside orders. By varying θ the position *I* of the inside order may be made as close as desired to the extended plane of the grating. In this way the angle $\theta - \alpha$, which we shall call β , can be made very small, resulting in a large dispersion. For the first inside order

$$\frac{d\alpha}{d\lambda} = \frac{1}{D\beta}. \quad (3)$$

Experimentally it has been found that there is a practical lower limit to the value of β ; otherwise the dispersion could be made greater without limit as the angle β decreases. It is of interest to note that the dispersion is independent of both λ and θ .

For outside orders the theoretical maximum dispersion is obtained when $\sin(\theta + \alpha)$ is a minimum. This is the case when $\theta = 0$. The dispersion for outside orders then becomes (neglecting higher powers of $n\lambda/D$)

$$\frac{d\alpha}{d\lambda} = \frac{1}{D} \left(\frac{D}{2\lambda} \right)^{1/2} n^{1/2}.$$

If r represents the ratio between the dispersion of the first inside order and that of the maximum theoretical value of the n th outside order, then

$$r = \frac{1}{\beta} \left(\frac{2\lambda}{D} \right)^{1/2} \frac{1}{n^{1/2}}.$$

Actually the ratio will be larger than this since it is not possible to make $\theta=0$. In some cases in this experiment the dispersion obtained with the first inside order was equal to twelve times the theoretical maximum for the first outside order. To obtain the same dispersion in an outside order would require going to the 150th order.

THE X-RAY SPECTROGRAPH

Fig. 2 shows a horizontal cross section of the spectrograph and x-ray tube. The body of the spectrograph consisted of a brass tube 8 inches in diameter and 40 inches long. To one end-plate was attached the water-

Fig. 2. Horizontal cross-section of the spectrograph and x-ray tube.

cooled metal x-ray tube X . The targets used consisted of small slabs of metal dove-tailed into the face of a water-cooled copper support. The tungsten filament was supported in the center of a water-cooled iron focusing cup.

To the same end-plate was attached a bed-plate on which the slit system, grating support, plate holders etc. were fastened. In order to collimate the rays and to exclude as much of the light from the incandescent tungsten filament as possible, the slit system S consisted of five slits. The two end slits, separated by a distance of 18 centimeters, were 0.05 mm wide; the three intermediate ones, 0.10 mm. By the passage through these slits the intensity of the light was so greatly diminished that it gave little difficulty. No trouble was experienced in the alignment of the slits in as much as the system consisted of two halves, half of each of the several slits being care-

fully machined into each metal piece, the two separate pieces then being clamped together.

The glass grating *G*, ruled 600 lines per millimeter, was mounted on a table which could be turned through any desired angle by means of a train of gears controlled from the rear end of the spectrograph near the end-plate *M*. This table, in turn, was mounted on a slide so that the grating could be removed from the path of the x-rays, this movement also being controlled from the rear end. The mechanism was so constructed that either operation could be performed without disturbing the setting of the other, and also so that definite settings could be reestablished with sufficient accuracy.

The plate holder *A* served to hold a plate which intercepted the lower half of the radiation coming from the grating. The upper half was recorded on a plate placed in the holder *B*. Plate *A* was made perpendicular to the direct beam as follows. One side of the slit system was removed, and a straight iron bar carefully clamped to the other half. With a precision square, *A* was made perpendicular to the bar within a few minutes of arc. *B* was then made parallel to *A* by means of an inside micrometer, this operation serving also to obtain the distance between the two plate holders. This distance was 37.982 cm.

All of the apparatus described thus far was mounted as one unit. It could be removed from the main body of the spectrograph at any time for purposes of adjustment.

After adjustment this unit was placed in the spectrograph, a sulphur-free rubber gasket being placed between the end-plate and the body. Plates (Eastman process) were put in holders *A* and *B*, and the spectrograph evacuated to a pressure of about 2×10^{-4} mm. A pressure considerably lower than this was maintained in the x-ray tube by means of a separate set of mercury vapor pumps. An exposure of from one to twelve hours was made, depending on the intensity of the radiation. After about twenty minutes exposure the reflected beam was covered with a small screen (operated by an electromagnet) to prevent over exposure and fogging. The exposure being completed, air was admitted, the end-plate *M* taken off and the grating removed from the path of the beam. After reevacuation the direct beam was exposed for a minute or two.

A small vessel containing phosphorus pentoxide was kept inside the spectrograph to absorb water vapor. The life of the tungsten filament was increased greatly by having a liquid air trap close to the x-ray tube to take up moisture.

The current through the x-ray tube varied from 15 to 40 milliamperes. Because a transformer having rather high secondary resistance was used it was not practicable to attempt to measure the effective voltage on the target, which was much lower than the inverse voltage across the self rectifying tube. It may be estimated that the effective voltage varied from 4000 to 12000 volts.

THE SPECTRA

Fig. 3 shows typical spectra obtained. These particular spectrograms, having nearly equal values of θ , were selected to show the relative displacement of corresponding lines and the increased dispersion with smaller values of β . The L_α and L_β lines of zinc are not resolved. The corresponding lines

Fig. 3. Typical L series spectra of Zn, Cu and Ni. D is the direct beam, R the reflected beam and X is light diffracted past edge of grating.

of copper overlap, the more intense L_α line being to the left. The lines of nickel are resolved. Since about the same wave-length difference exists between these lines, the spectra show the increase in dispersion as the inside order approaches the plane of the grating. Of the three spectrograms shown only that of nickel is useful in making measurements on the L_β line.

Fig. 4.

It was found that the first inside order from the grating used was much greater in intensity than the outside orders. This fact, combined with the great dispersion obtained with inside orders, contributed greatly to the success of the work. It was also found that the intensity of the L radiation from

the elements studied depended greatly upon the operating conditions of the tube. It was most intense when the temperature of the focal spot was maintained very close to the melting point. With this condition the spot was kept very clean.

The measurement of the plates and the calculation of results can best be described with reference to Fig. 4. The size of the ruled surface (2 cm \times 2 cm), the width of the x-ray beam (approx. 0.1 mm) and the magnitude of the grazing angle (more than $2^{\circ}25'$) make it possible to have the entire beam "reflected" from the ruled surface of the grating. Hence all measurements may be made to the centers of the recorded lines. The positions of the lines on the plates were taken as a mean of at least ten independent settings on a Gaertner comparator. The probable error in the readings was usually less than 0.003 mm. The distance e of plate A from the grating and the angles 2θ and $2\theta - \alpha$ were obtained as indicated. By subtraction α was found and substitution made in Eq. (2) to obtain the wave-length.

The results of the measurements are shown in Table I, which gives both the wave-length in angstroms and the value of $(\nu/R)^{1/2}$.

TABLE I.

Element	$L\alpha_{12}$		$L\beta$		Ll		$L\eta$	
	λ	$(\nu/R)^{1/2}$	λ	$(\nu/R)^{1/2}$	λ	$(\nu/R)^{1/2}$	λ	$(\nu/R)^{1/2}$
30 Zn	12.25	8.63	11.96	8.73	14.02	8.06		
29 Cu	13.37	8.26			15.33	7.71	14.95	7.81

23 V	24.31	6.12			27.70	5.73		
22 Ti	27.48	5.76						
20 Ca					39.63	4.79		

DISCUSSION

Fig. 5 is a Moseley diagram of the results. The results here given are all higher than those obtained by Thoraues¹ and Shearer.² This is in accord with the results obtained by other experimenters.¹³ Kellström has reported measurements on most of these lines, using outside orders which did not permit the resolution of the α and β lines or of the l and η lines. His values for the α and l lines are less than those reported here. This is, of course, due in part to the added weight of the unresolved β and η lines. However, in the case of the β line at least, the relative intensity is so much smaller than that of the α line that the wave-length determined from the measurement of the unresolved lines is far from the mean of the two component wave-lengths. Comparison of the results of the two experiments is therefore limited. This is further complicated by the fact that Kellström has made his measurements by comparison with the K_{α} line of aluminum as obtained from crystal

¹³ A. H. Compton, Jour. Franklin Inst. 208, 605 (1929).

measurements. This would also make his measurements lower. In view of these considerations the agreement between the two experiments is very satisfactory, with the exception of the l line of calcium for which Kellström

Fig. 5. Moseley diagram for L -series lines.

finds a value three percent higher than the value here given. Unfortunately the author recorded this line on but one plate and could not therefore check this wave-length carefully. In all but a few cases, however, sufficient values were obtained to give a probable error less than 0.01A.

Fig. 6. Values of θ for which the inside order should be in the plane of the grating.

In order to resolve the α and β lines as well as the l and η lines it was necessary to rotate the grating so that the inside orders occurred close to the plane of the grating. Consequently each element required at least two

independent settings; one to resolve the α and β lines, the other to resolve the l and β lines. In order to facilitate this operation the angle θ was calculated for which the inside order should be in the plane of the grating. Fig. 6 shows this value of θ in degrees plotted against the corresponding value of λ in angstrom units. In actual practice θ was made a little larger than this critical value.

For most of the elements in this region the L_α line is really two lines, the $L\alpha_1(M_{33}-L_{22})$ and the $L\alpha_2(M_{32}-L_{22})$. According to Foote's extension of Stoner's arrangement of the electrons the M_{33} level disappears with vanadium and the M_3 level with calcium. This means that neither of the two components of the $L\alpha_{12}$ line should be observed for calcium. Reference to Fig. 1 shows that it was not observed in this experiment although Kellström¹² finds it present. The $L\beta_1(M_{32}-L_{21})$ line should also disappear with calcium.

In conclusion I wish to express my indebtedness to Professor A. H. Compton of the University of Chicago under whose direction the experimental work was done.

THE CYBOTACTIC (MOLECULAR GROUP) CONDITION IN LIQUIDS; THE NATURE OF THE ASSOCIATION OF OCTYL ALCOHOL MOLECULES

BY G. W. STEWART

DEPARTMENT OF PHYSICS, UNIVERSITY OF IOWA

(Received January 15, 1930)

ABSTRACT

In resumé twelve experimental lines of evidence are cited in favor of the adoption of the molecular group theory of the nature of liquids. This theory is assumed in the interpretation of results with octyl alcohols.

The following twenty-two octyl alcohols were used: octanol -1, -2, -3, -4, 2-methyl heptanol -1, -2, -3, -4, 3-methyl heptanol -1, -2, -3, -4, 4-methyl heptanol -1, -2, -3, -4, 5-methyl heptanol -1, -2, -3, 6-methyl heptanol -1, -2, -3.

The value of the effective diameter of the primary normal alcohols is approximately 4.5 Å. With these octyl alcohols the increase for OH and CH₃ in a branch is approximately 0.0 Å and 0.24 to 0.75 Å respectively. When attached to the same carbon atom the increase caused thereby is not noticeable. These results are in fair agreement with previous similar measurements of isomers with other primary alcohols.

Two types of association were found. When the OH group is attached to the end or next to the end of the alcohol molecule, two of these molecules are associated end to end, the lengths of the chains being in the same straight line. On the other hand when the OH group is attached to any other carbon atom, the molecules are associated side by side. This is shown by the planar distances in the direction of the molecule which indicate in the first case the length of two molecules and in the second case the length of a single molecule.

DURING the past four years evidence has been accumulating in favor of the view that in liquids in general there exist temporary, fairly orderly, not sharply defined molecular groups. A brief resumé of that evidence, as an introduction to the present experiments, is opportune. Skepticism concerning the correctness of this conception of molecular groups is natural, since it has formerly been accepted that the molecular motions in a liquid are somewhat independent. Moreover it is known that molecules of a gas, which are certainly not orderly, will give x-ray diffraction haloes.¹

EVIDENCE FOR THE CYBOTACTIC CONDITION

It will be the purpose of this statement of evidence to present the material merely in outline. The reader can easily follow the argument by studying the experimental results mentioned in each case. For the sake of simplicity the references will be limited but the articles to which references are made contain the complete bibliography. It is believed that the evidence establishes the group theory as one worthy of confidence. The chief points will be now enumerated. All the experiments refer to x-ray diffraction.

¹ Debye, Phys. Zeits. 30, 524 (1929); 31, 142 (1930).

1. Scattering centers at random would produce a large scattering near 0° , for in the terms of a wave theory, the nearer the approach to 0° the more nearly the agreement in phase. But crystals and crystal powders would, if ideal, give zero diffraction near but not at 0° . With them, interference would produce zero intensity excepting at angles of regular reflection.² Now it is found that in liquids, in general, we find the diffraction near zero to be similar to that of crystal powders and not to amorphous substances. The author and his co-workers³ habitually approach zero diffracting angle to the limit permitted by the resolving power of the instrument, $24'$, and they find the intensity small and decreasing as 0° is approached.
